# Unusual and unprecedented rings and cages derived from main group elements

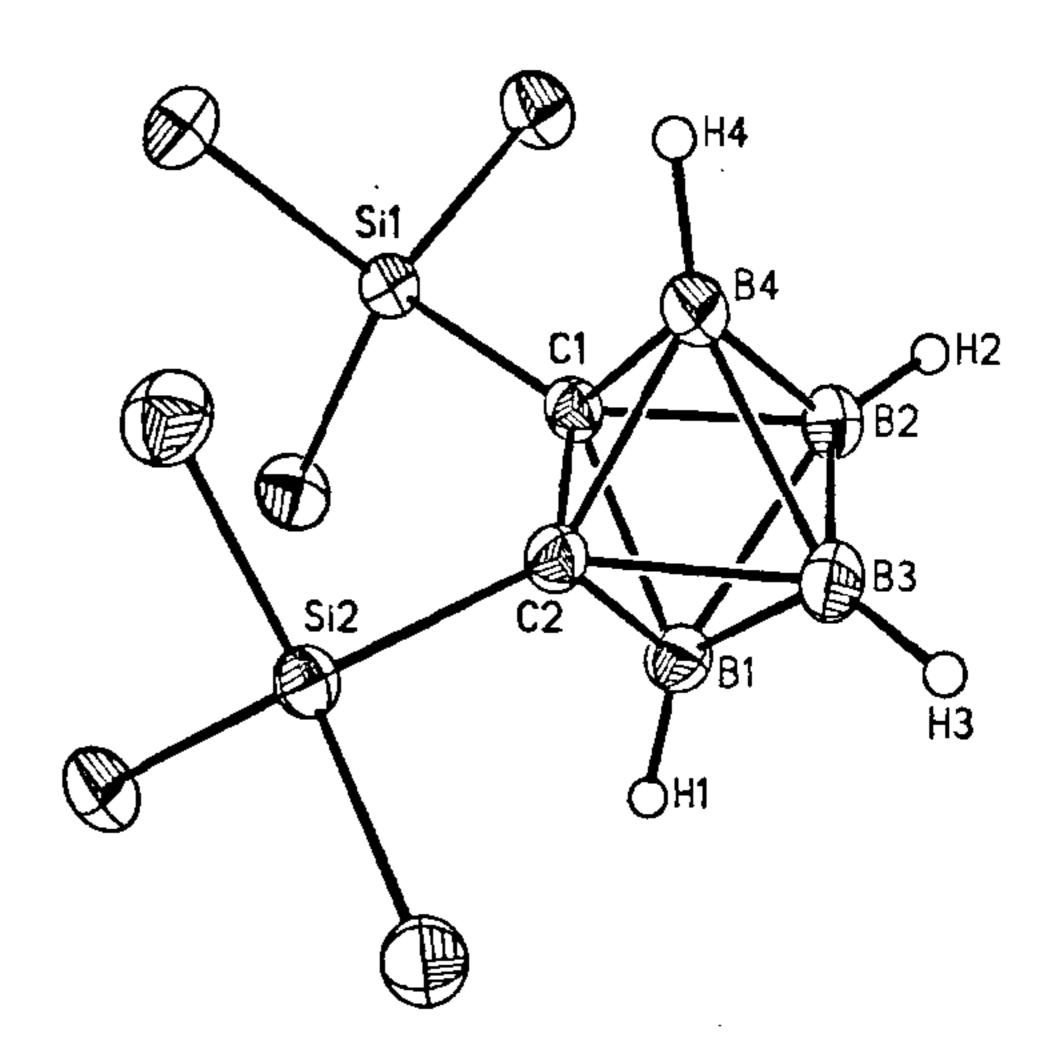

#### Narayan S. Hosmane

Department of Chemistry and Biochemistry, The Michael Faraday Laboratories, Northern Illinois University, DeKalb, Illinois 60115-2862, USA

This research account presents our significant recent findings in the area of small cage main group metallacarboranes during the past several years. The highlights of these findings are as following: (1) The reactivity study on the carbons apart C4B8-carborane led to the introduction of an unusual carborane species that acts as a restricted electron-acceptor by removing only the valence electrons of a group 1 or group 2 metal, thus forming the corresponding alkali and alkaline earth metal compounds. Further reactivity study of these species in solvent extraction of radioactive cesium metal ion (137Cs+) from nuclear wastes has rekindled our interest to explore new avenues in this area of main group metallacarborane research. (2) The syntheses and structures of main group metallacarboranes have exemplified their rich structural and coordination chemistry beyond their existence as versatile synthons for the production of other metallacarboranes of d- and f-block elements. (3) Synthesis and reactivity study on half- and fullsandwich gallacarboranes opened up the possibility of using such compounds as precursors in the formation of conducting materials. (4) Even though two germanium atoms are present formally in +2 and +4 oxidation states, the reactivity study on the mixedvalence digermacarboranes with Lewis bases shows no indication of exo-polyhedral Ge(IV) atom being the Lewis acid site. And finally, (5) our research has demonstrated that the 'electron-deficient' cages can be quantitatively transformed into the corresponding 'electron-precise' heterocyclic rings.

THERE has been extensive research reported on the chemical and structural properties of the metallacarboranes in the pentagonal bipyramidal ( $MC_2B_4$ ) and the icosahedral ( $MC_2B_9$ ) cage systems<sup>1</sup>. These complexes are generally synthesized by the reaction of the monor dianions of the nido- $C_2B_4$  or  $C_2B_9$  carboranes with suitable metal reagents. Much of the emphasis for these studies comes from the fact that the two nido-carboranes have 6  $\pi$  electrons delocalized on a  $C_2B_3$  open pentagonal face that are very similar to the primary metal-bonding orbitals of the cyclopentadienide ligand,  $[C_5H_5]^-$ . Our research in this area has involved syn-

thetic, structural, reactivity and theoretical studies on the full- and half-sandwich metallacarboranes derived from the interactions of  $[nido-2-(SiMe_3)-n-(R)-2,n-C_2B_4H_4]^{2-}$   $[n=3, 4; R=SiMe_3, Me, H]$  with main group<sup>2</sup>, d-group<sup>3</sup>, and f-group metals<sup>4</sup>. Here we report some of our latest results in this fascinating area of carborane research.

e-mail: nhosmane@niu.edu

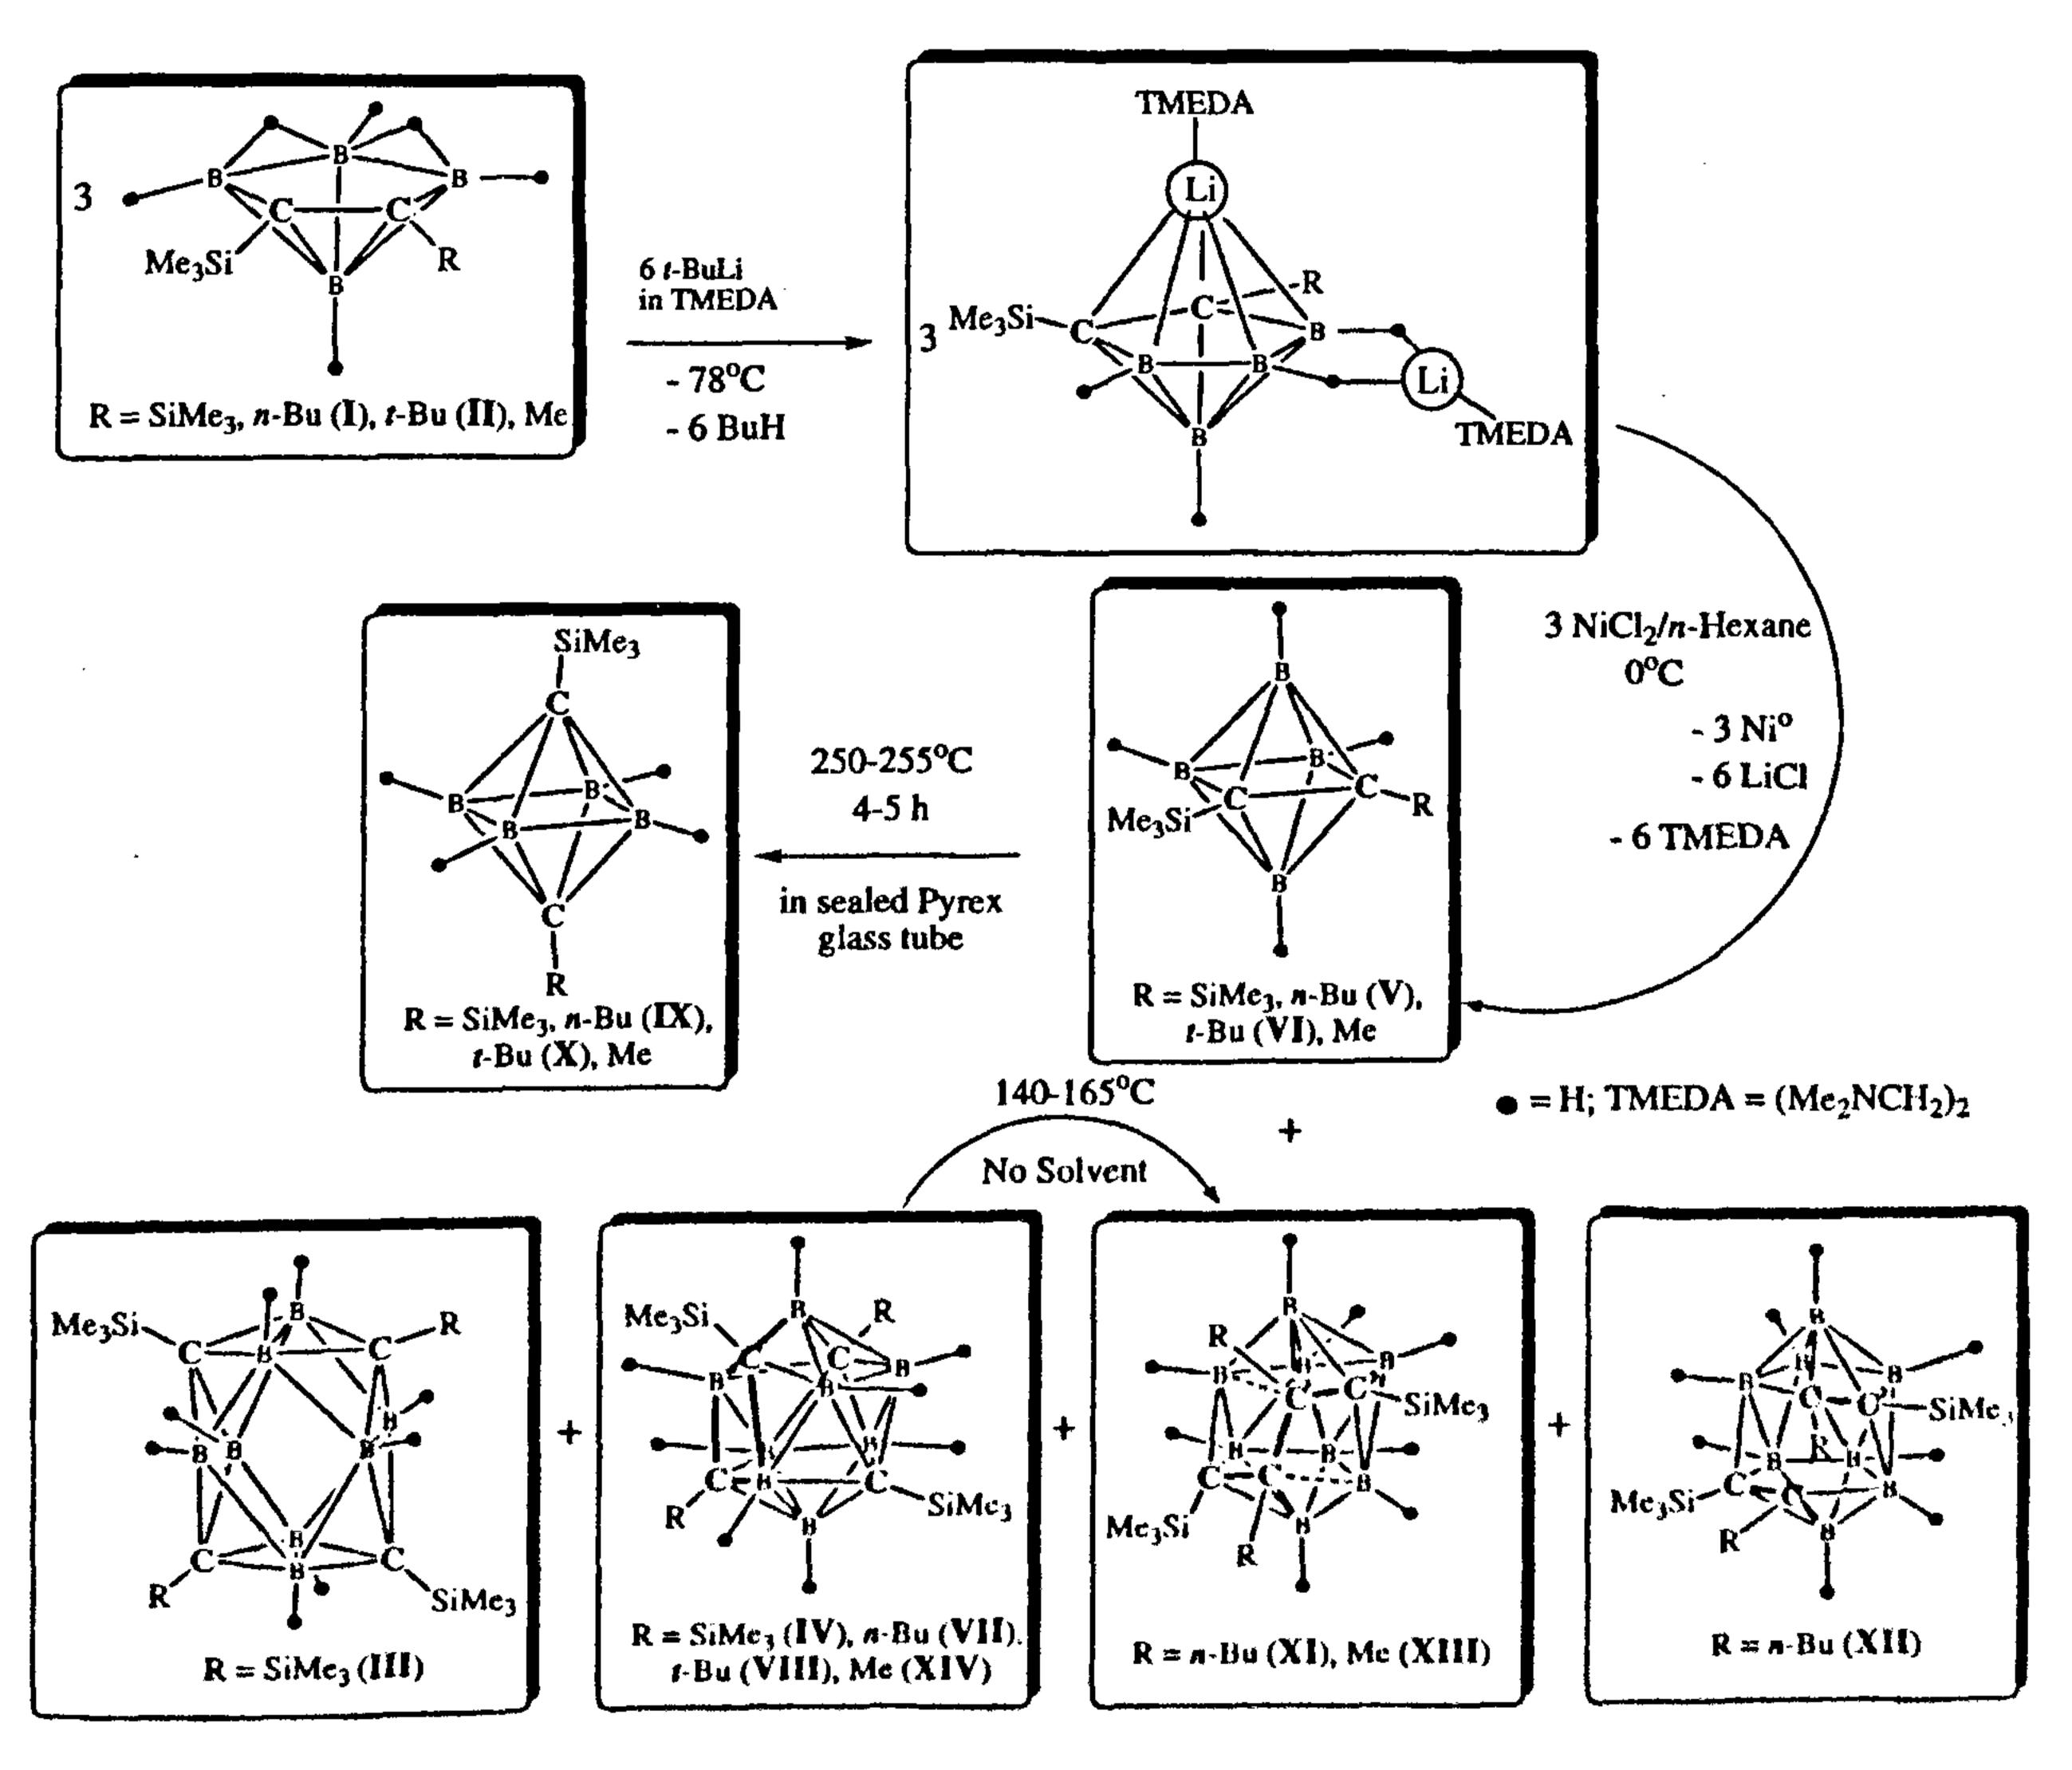

This paper is dedicated to Prof. S. S. Krishnamurthy on the occasion of his 60th birthday.

#### Syntheses of C<sub>2</sub>B<sub>4</sub> and C<sub>4</sub>B<sub>8</sub>-carboranes

The reaction of the 2,3-C<sub>2</sub>B<sub>4</sub>-carborane dianion with NiCl<sub>2</sub> in hexane did not give the nickelacarborane but instead underwent oxidative cage closure reactions to produce the corresponding closo-1-(SiMe<sub>3</sub>)-2-(R)-1,2-C<sub>2</sub>B<sub>4</sub>H<sub>4</sub> (see Figure 1) and nickel metal<sup>3</sup>. In addition, we observed an accompanying oxidative cage fusion process that led to the formation of the novel tetracarbon carboranes,  $nido-2,4,x,y-(SiMe_3)_4-2,4,x,y-C_4B_8H_8$  (x=7, y = 9, (III in Scheme 1); x = 6, y = 12, (IV in Scheme 1)) (refs 6, 7). Since all cage carbon atoms are separated by at least one boron atom, they will subsequently be referred to as the 'carbons apart' isomers. Grimes and co-workers first reported on the syntheses, structures and reactivities of several tetracarbon carboranes, all of which possessed the common structural feature. The cage carbons were localized on one side of very distorted icosahedral cages<sup>8-12</sup>. In one of these 'carbons carbon adjacent' isomers the atoms were

bonded contiguously in a Z-shaped pattern<sup>10</sup>, while in the other, the middle C-C bond was ruptured leading to a more open structure<sup>11</sup>. However, the proximate locations of the cage carbons were maintained in all isomers. These 'carbons adjacent' compounds were obtained as the products from the mild air oxidation of the metalhydride complexes  $(R_2C_2B_4H_4)_2MH_x$   $(M = Fe (x = 2), Co (x = 1); R = CH_3, C_2H_5, n-C_3H_7 and CH_2C_6H_5)$  (refs 8, 9, 12). On the other hand, when the dianions, [nido-2-(SiMe<sub>3</sub>)-3-(R)-2,3-C<sub>2</sub>B<sub>4</sub>H<sub>4</sub>]<sup>2-</sup>  $(R = SiMe_3, n$ -Bu or t-Bu) were oxidized by NiCl<sub>2</sub> a completely different set of tetracarbon carboranes were produced<sup>6,7</sup>.

In these trimethylsilyl-substituted compounds, the cage carbons were more evenly dispersed throughout the cage, being separated by at least one boron to give, the so-called 'carbon apart' compounds. One of these, the nido-2,4,7,9-(SiMe<sub>3</sub>)<sub>4</sub>-2,4,7,9-C<sub>4</sub>B<sub>8</sub>H<sub>8</sub>, is of particular interest in that it is a 12-vertex cage whose structure is based more on a cuboctahedron than an icosahedron (Figure 2) (refs 6, 7). This geometry is of interest in that

Scheme 1. Syntheses of closo-C2B4- and nido-C4B8-carboranes.

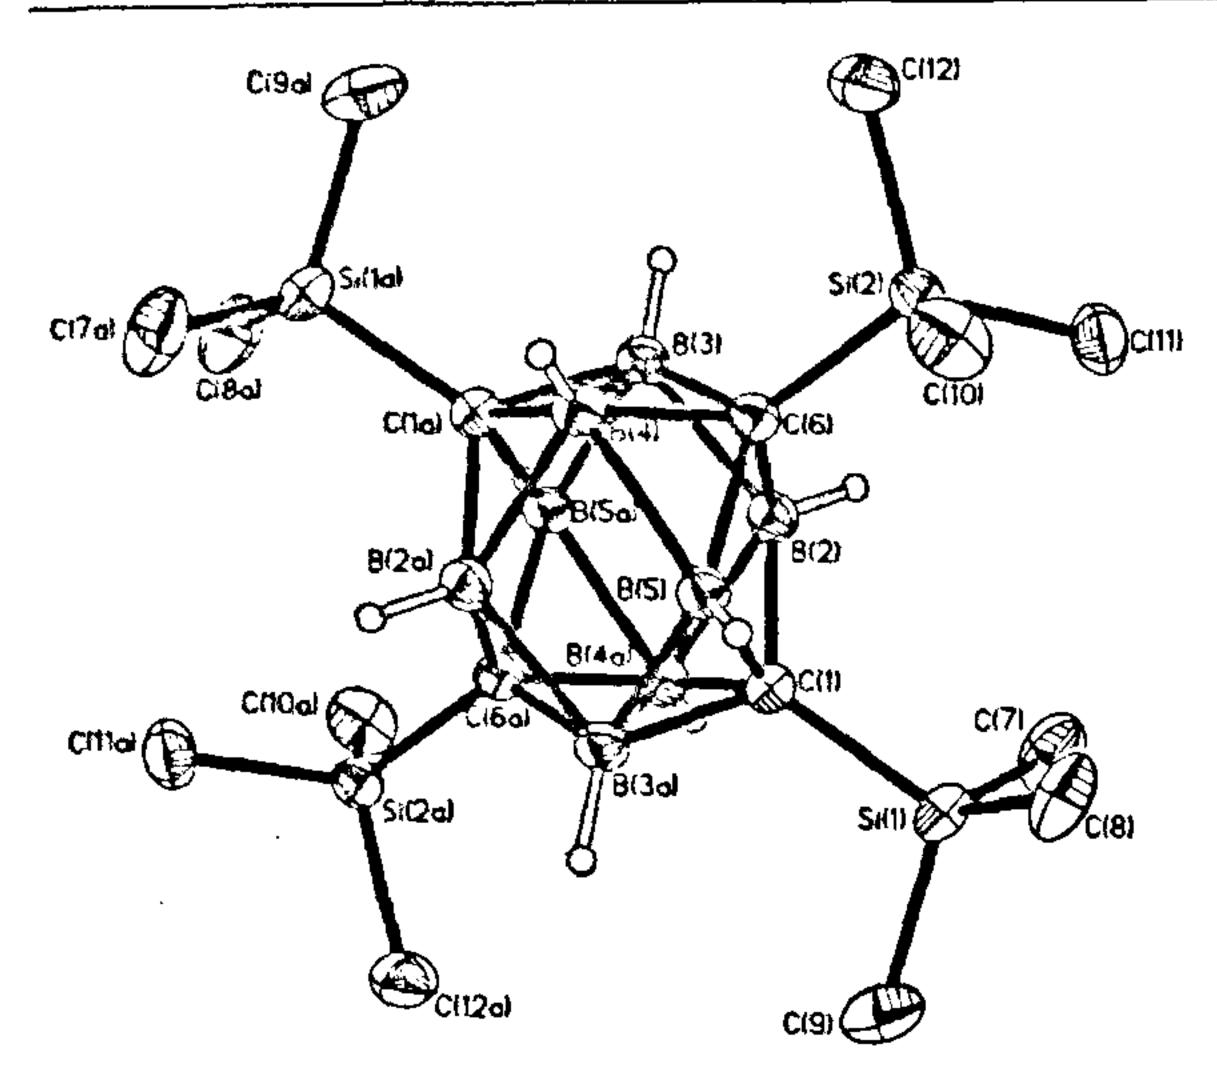

Figure 2. nido-2,4,7,9-(SiMe<sub>3</sub>)<sub>4</sub>C<sub>4</sub>B<sub>8</sub>H<sub>8</sub>.

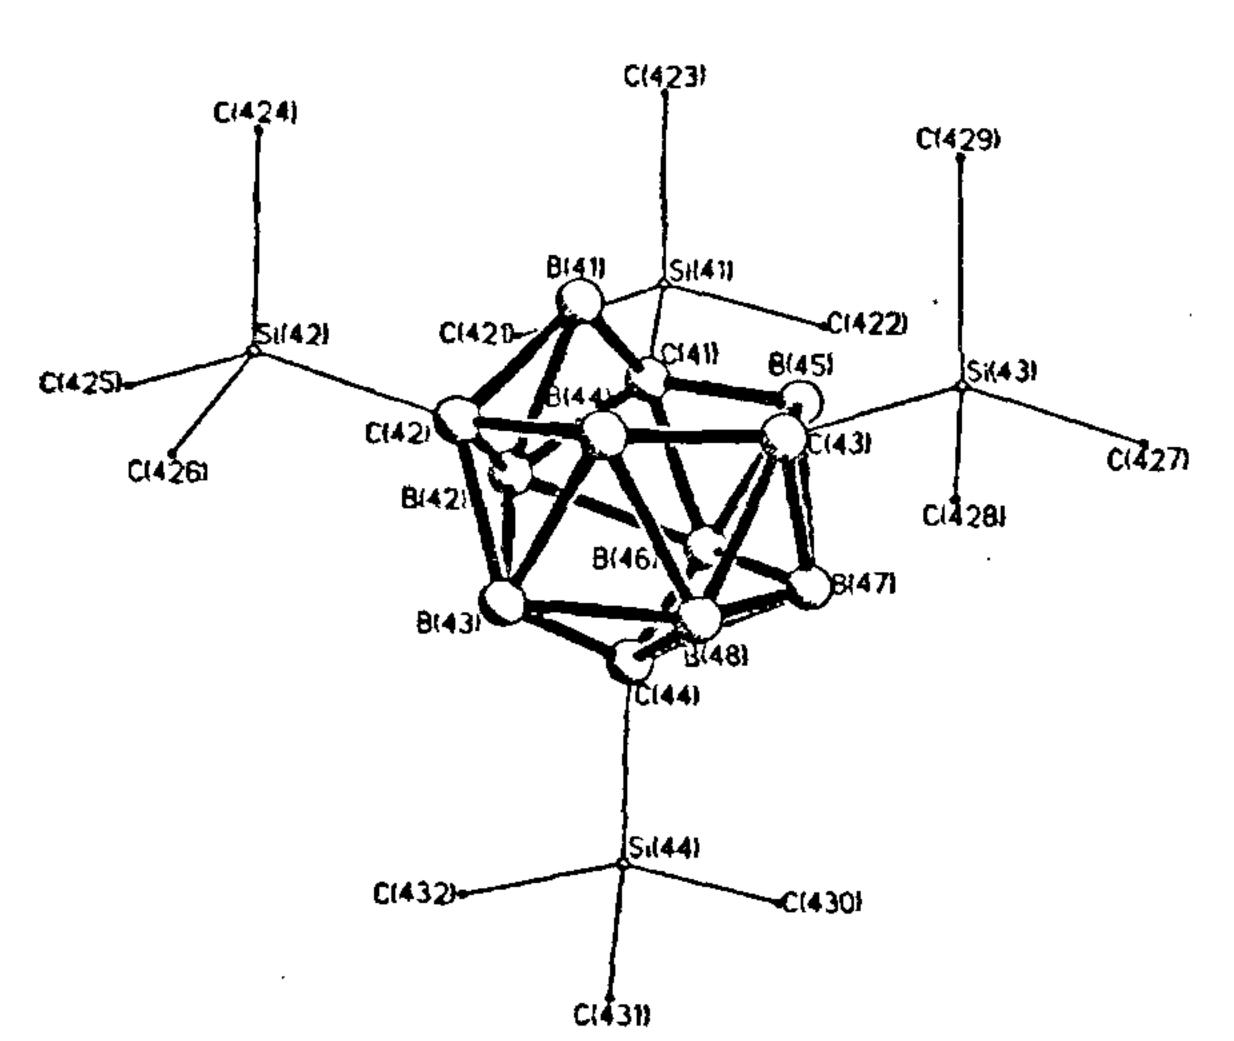

Figure 3. nido-2,4,6,12-(SiMe<sub>3</sub>)<sub>4</sub>C<sub>4</sub>B<sub>8</sub>H<sub>8</sub>.

a cuboctahedral structure was proposed by Lipscomb for the key intermediate in the diamond-square-diamond (DSD) mechanism for the rearrangement of closo-1,2- $C_2B_{10}H_{12}$  to close-1,7- $C_2B_{10}H_{12}$  (ref. 13). The other isomer, exemplified by  $nido-2,4,6,12-(SiMe_3)_4-2,4,6,12-$ C<sub>4</sub>B<sub>8</sub>H<sub>8</sub>, had a more traditional *nido*-cage structure with an open C<sub>3</sub>B<sub>3</sub> face surmounting a B<sub>5</sub> ring and an apical cage carbon (Figure 3) (ref. 7). Most of the C<sub>4</sub>B<sub>8</sub> carboranes exhibit nonrigid stereochemistry, showing multiple isomerization or fluxional behaviour in solution<sup>7,8,11</sup>. When two of the SiMe<sub>3</sub> moieties were substituted by less bulkier n-butyl groups, both 'carbons adjacent' and 'carbons apart' isomers of C<sub>4</sub>B<sub>8</sub>-carborane were isolated. Moreover, the geometries of these 'carbons adjacent' isomers are identical to those observed by Grimes (Figures 4 and 5) (ref. 7).

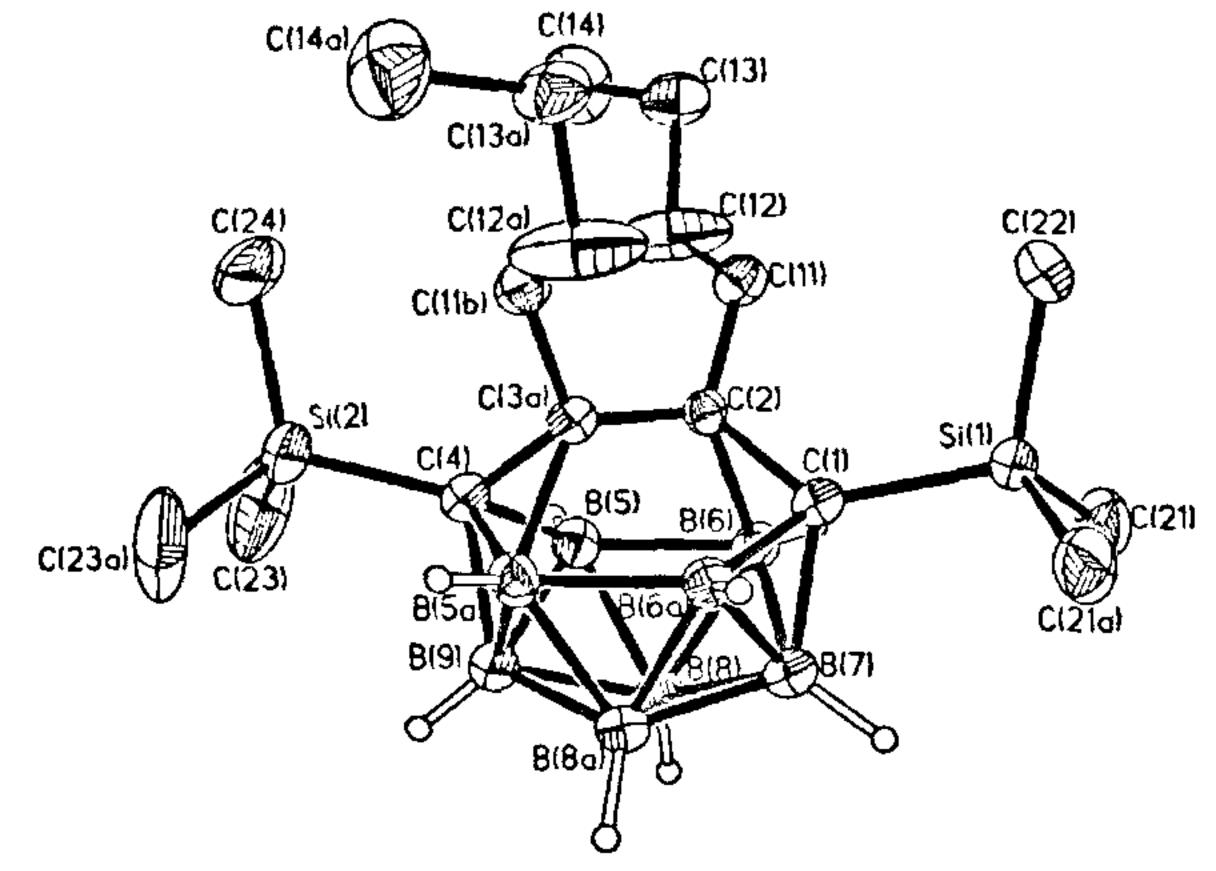

Figure 4.  $1,4-(SiMe_3)_2-2,3-(n-Bu)_2C_4B_8H_8$ .

#### Reactivities of 'carbons apart' C<sub>4</sub>B<sub>8</sub>-carboranes

Both 'carbons adjacent' and 'carbons apart' C<sub>4</sub>B<sub>8</sub>carboranes can be reduced to give dianionic cages, which on metallation produced, at least formally, 13vertex metallacarboranes. Grimes and co-workers have reported the syntheses of a large number of d-block metallacarboranes in the 'carbons adjacent' system<sup>1(a),14,15</sup>. Multiple structures were found for a particular carborane and metal group. These were thought to arise from the metal coordination of the numerous isomers of the C<sub>4</sub>B<sub>8</sub> dianions that were present in reaction solutions. While the reports on the metallacarboranes derived from the 'carbons adjacent' carboranes are fairly extensive, the only metallacarboranes in the 'carbons apart' system that have been published are those contained in our preliminary reports on  $[(THF)_4Li][(SiMe_3)_4C_4B_8H_9],$  [exo-Cs(TMEDA)-1-Cs- $2,4,7,9-(SiMe_3)_4-2,4,7,9-C_4B_8H_8$  $(THF)_2Mg$ and (SiMe<sub>3</sub>)<sub>4</sub>C<sub>4</sub>B<sub>8</sub>H<sub>8</sub> whose synthetic pathways are shown in Scheme 2 (refs 16, 17). According to this scheme the room temperature reaction between a TMEDA soluof 2,4,7,9-tetracarba-*nido*-dodecaborane (12),

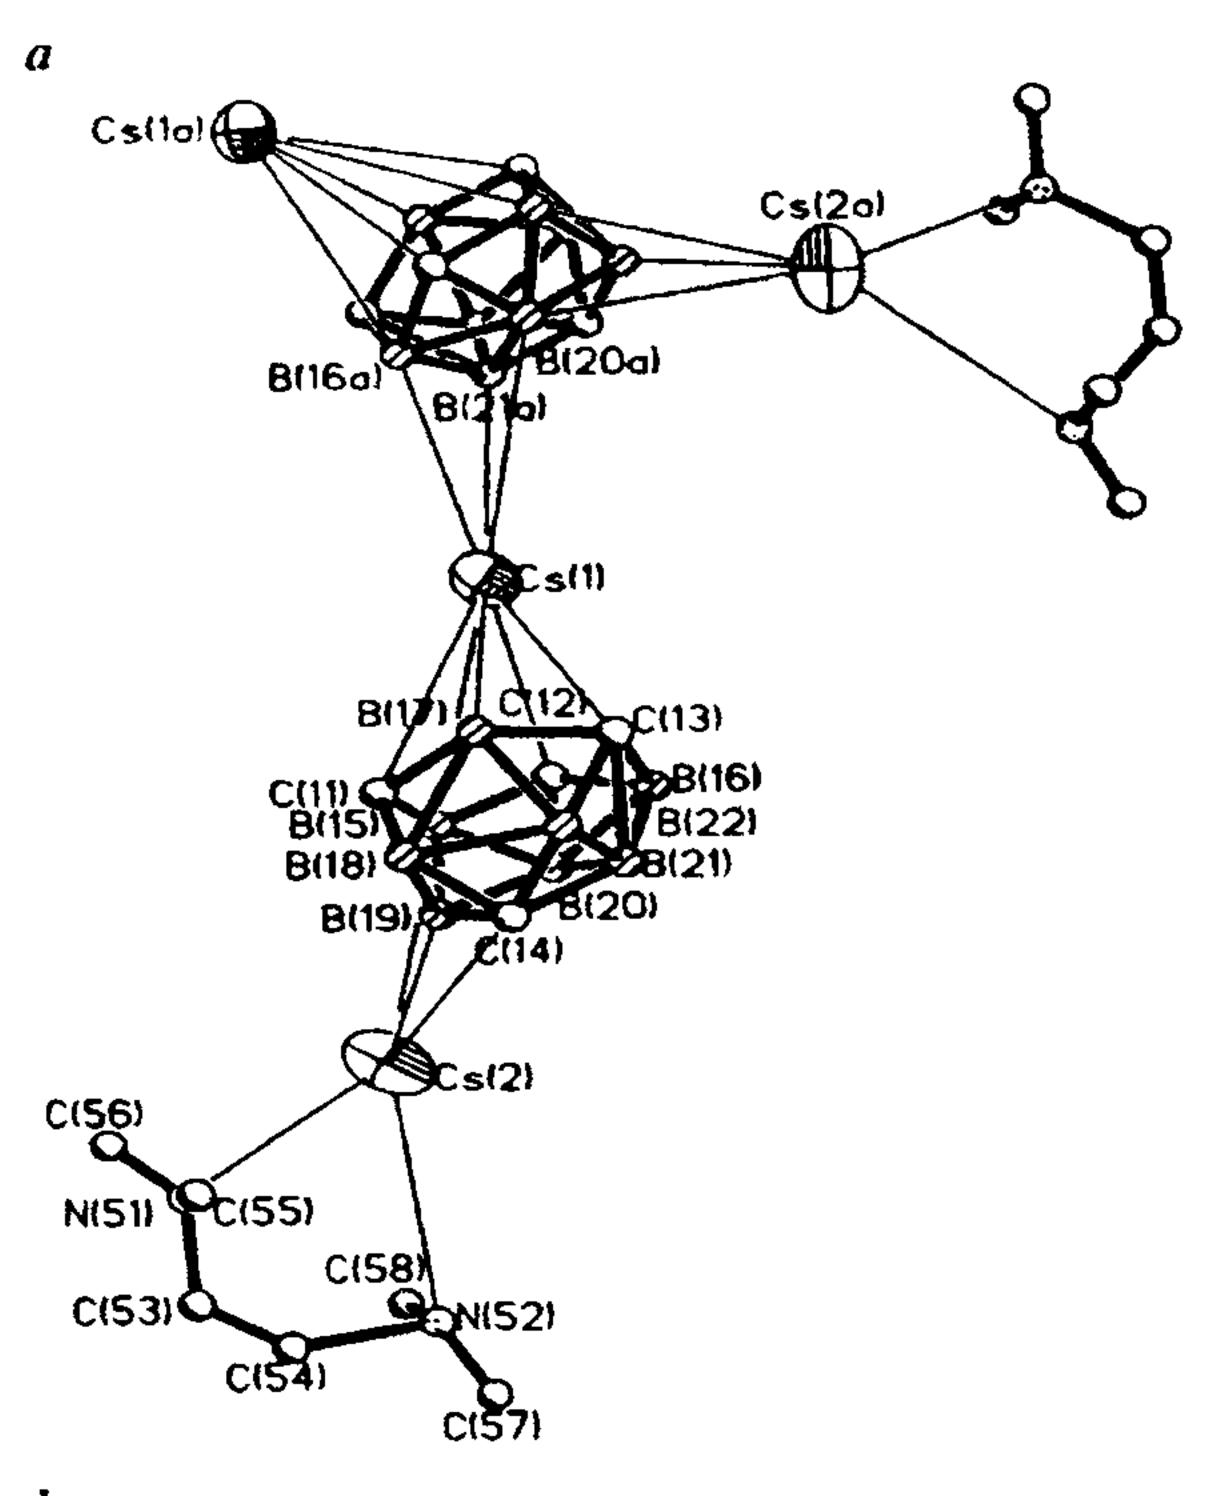

Scheme 2. Syntheses of tetracarbon-carborane compounds of group 1 and group 2 metals.

(SiMe<sub>3</sub>)<sub>4</sub>C<sub>4</sub>B<sub>8</sub>H<sub>8</sub>, and excess cesium metal, in the absence of naphthalene and aromatic solvents, produced novel EPR-silent species, [exo-[(\mu-H)<sub>2</sub>Cs the  $(TMEDA)]-1-Cs-2,4,7,9-(SiMe_3)_4-2,4,7,9-C_4B_8H_8]_n$ , the first example of a cesium compound in which the metal interacts with the carborane cage sequentially to form repeating metal-carborane units<sup>17</sup>. The X-ray diffraction study on the cesium complex confirmed its polymeric structure in which each C<sub>4</sub>B<sub>8</sub>-carborane fragment serves as a ligand to two Cs atoms, bonded to one through an open six-membered face and to the other via upper- and lower-belt M-H-E (where E = B or C) interactions (Figure 6) (ref. 17). This structural feature is somewhat similar to that of the Sr complex of the [C<sub>2</sub>B<sub>10</sub>H<sub>12</sub>]<sup>2</sup> ligand, reported by Hawthorne and coworkers 18. However, the interatomic distances of Cs to the carborane cages are such that it could be regarded as a cesiumcarborane complex in which some degree of interaction

exists between the metal and the  $\pi$ -electron density on the carborane cage. Since this cesium compound can also be prepared by an ion-exchange reaction directly from lithium, sodium or potassium salts of the  $C_4B_8$ -cage (see Figure 6 b), further study of this and related compounds in solvent extraction of radioactive cesium metal ( $^{137}Cs$ ) from nuclear waste is envisioned.

Under similar reaction conditions, the 'carbons apart' tetracarbon carborane, nido-2,6-(R)<sub>2</sub>-4,12-(SiMe<sub>3</sub>)<sub>2</sub>-2,4,6,12-C<sub>4</sub>B<sub>8</sub>H<sub>8</sub> (R = SiMe<sub>3</sub>, n-butyl), and several of its B-alkylated derivatives, react with Mg metal in THF to produce magnesacarboranes in yields ranging from 57% to 74% (Scheme 2) (refs 16, 19). Two types of cages were found, one in (THF)<sub>2</sub>Mg(SiMe<sub>3</sub>)<sub>4</sub>(B-Me)C<sub>4</sub>B<sub>7</sub>H<sub>7</sub> and the other in (L)<sub>2</sub>Mg(SiMe<sub>3</sub>)<sub>2</sub>(R)<sub>2</sub>(B-Y)C<sub>4</sub>B<sub>7</sub>H<sub>7</sub> (L = THF, R = SiMe<sub>3</sub>, Y = t-Bu; L = THF, R = SiMe<sub>3</sub>, Y = t-Bu; L = THF, R = SiMe<sub>3</sub>, Y = t-Bu; L = THF, R = SiMe<sub>3</sub>, Y = t-Bu; L = THF, R = SiMe<sub>3</sub>, Y = t-Bu; L = THF, R = SiMe<sub>3</sub>, Y = t-Bu; L = THF, R = SiMe<sub>3</sub>, Y = t-Bu; L = THF, R = SiMe<sub>3</sub>, Y = t-Bu; L = THF, R = SiMe<sub>3</sub>, Y = t-Bu; L = THF, R = SiMe<sub>3</sub>, Y = t-Bu; L = THF, R = SiMe<sub>3</sub>, Y = t-Bu; L = THF, R = SiMe<sub>3</sub>, Y = t-Bu; L = THF, R = SiMe<sub>3</sub>, Y = t-Bu; L = THF, R = SiMe<sub>3</sub>, Y = t-Bu; L = THF, R = SiMe<sub>3</sub>, Y = t-Bu; L = THF, R = SiMe<sub>3</sub>, Y = t-Bu; L = THF, R = SiMe<sub>3</sub>, Y = t-Bu; L = THF, R = SiMe<sub>3</sub>, Y = t-Bu; L = THF, R = SiMe<sub>3</sub>, Y = t-Bu; L = THF, R = SiMe<sub>3</sub>, Y = t-Bu; L = THF, R = SiMe<sub>3</sub>, Y = t-Bu; L = THF, R = SiMe<sub>3</sub>, Y = t-Bu; L = THF, R = SiMe<sub>3</sub>, Y = t-Bu; L = THF, R = SiMe<sub>3</sub>, Y = t-Bu; L = THF, R = SiMe<sub>3</sub>, Y = t-Bu; L = THF, R = t-Bu; L = THF, R = t-Bu; L = t

ron atoms, as well as electron deficient fragments (see Figure 7). On the other hand, the reactions of *nido*-2,4,6,12-(SiMe<sub>3</sub>)<sub>4</sub>-2,4,6,12-C<sub>4</sub>B<sub>8</sub>H<sub>8</sub> with the group 1 metals followed a different course in which two distinct steps occurred (Scheme 2). The first step formed the

paramagnetic, [(SiMe<sub>3</sub>)<sub>4</sub>C<sub>4</sub>B<sub>8</sub>H<sub>8</sub>] intermediate, which, in a slower step, reacted with a second equivalent of the metal to give the diamagnetic [(SiMe<sub>3</sub>)<sub>4</sub>C<sub>4</sub>B<sub>8</sub>H<sub>8</sub>]<sup>2-</sup>. For the lighter metals, this dianion picked up a proton to give the products,  $[(THF)_4M][(SiMe_3)_4C_4B_8H_9]$  (M = Li, Na or K), in 35-54% yield<sup>19</sup>. In the case of Cs, no protonation occurred and the final product was a polymeric dicesiacarborane, [exo-Cs(TMEDA)-1-Cs(SiMe<sub>3</sub>)<sub>4</sub>C<sub>4</sub>B<sub>8</sub>H<sub>8</sub>]<sub>n</sub>, isolated in 41% yield. In group 1 metallacarboranes, the lighter metal was solvated by four THF molecules and was not involved in the cage, while in cesium compound one Cs occupied an apical position above a C<sub>3</sub>B<sub>3</sub> open face of one carborane and bonded to a B<sub>3</sub> face of a neighbouring carborane. The second Cs, solvated by a TMEDA molecule, occupies an exo-polyhedral position and was not part of the polymeric chain (see Figure 6).

#### Reactivity of 'carbons adjacent' C<sub>4</sub>B<sub>8</sub>-carborane

A 'carbons adjacent' magnesacarborane, exo-(μ-H)<sub>3</sub>Mg(THF)<sub>3</sub>(SiMe<sub>3</sub>)<sub>2</sub>(Me)<sub>2</sub>C<sub>4</sub>B<sub>8</sub>H<sub>8</sub> was synthesized, in 81% yield, by the reaction of the metal with the (SiMe<sub>3</sub>)<sub>2</sub>(Me)<sub>2</sub>C<sub>4</sub>B<sub>8</sub>H<sub>8</sub> precursor. Single crystal X-ray diffraction studies showed the compound to be composed of an exo-polyhedral [Mg(THF)<sub>3</sub>]<sup>2+</sup> cation that is loosely bound to a [(SiMe<sub>3</sub>)<sub>2</sub>(Me)<sub>2</sub>C<sub>4</sub>B<sub>8</sub>H<sub>8</sub>]<sup>2-</sup> cage. This carborane polyhedron is best described as ten-vertex arachno-(SiMe<sub>3</sub>)<sub>2</sub>C<sub>2</sub>B<sub>8</sub>H<sub>8</sub> cage that subtends an electron precise MeC=CMe fragment (Figure 8) (ref 19).

## Conversion of carborane cage into electron-precise heterocyclic ring

The dominant structural patterns found in alkyl and aromatic hydrocarbons are reflections of the structures of elemental carbon (diamond or graphite) where added hydrogen atom across the C-C bonds gives 'electron precise-carbon hydrides'. In a similar way the structures of boron hydrides are reflections of the icosahedral units found in elemental boron. The replacement of a (BH) unit by a CH or CR unit gives the corresponding 'electron-deficient' carborane derivatives<sup>20</sup>. Although the magnesacarboranes in Figure 7 consisted of both electron-precise atoms and an electron-deficient carborane unit in a single cage framework, there have been no reports on the conversion of an electron-deficient carborane cage essentially into an electron-precise heterocyclic ring. As part of our exploration of new methodologies in this area, a neat sample of nido-2,3-(SiMe<sub>3</sub>)<sub>2</sub>-2,3-C<sub>2</sub>B<sub>4</sub>H<sub>6</sub> was reacted with a large excess of wet N,N,N,N-tetramethylethylenediamine (TMEDA) in vacuo with constant stirring at room temperature for 7 days that transformed the 'electron-deficient' carborane cage into a seven-membered 'electron-precise' heterocyclic ring, 1-trimethylsilyl-3,6-dimethyl-3,6-diaza-

### Reactivity of C<sub>2</sub>B<sub>4</sub>-carboranes with group 13 elements

There have been a number of reports on the syntheses, structures and reactivities of half-sandwich alkylgal-lacarboranes of both the 'carbons adjacent' and 'carbons

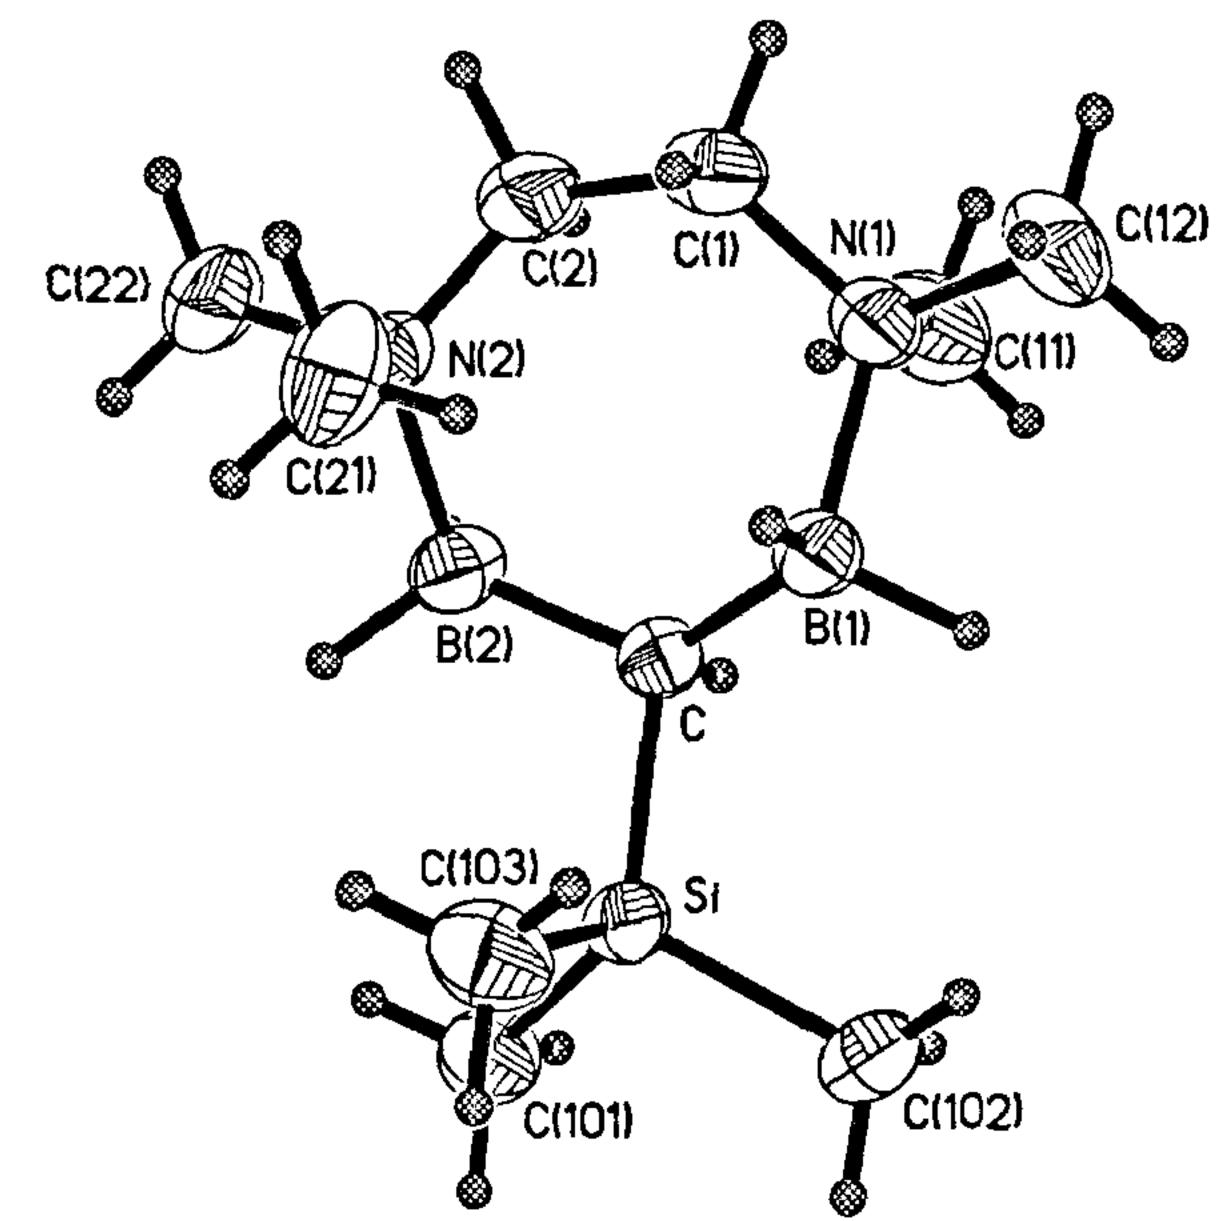

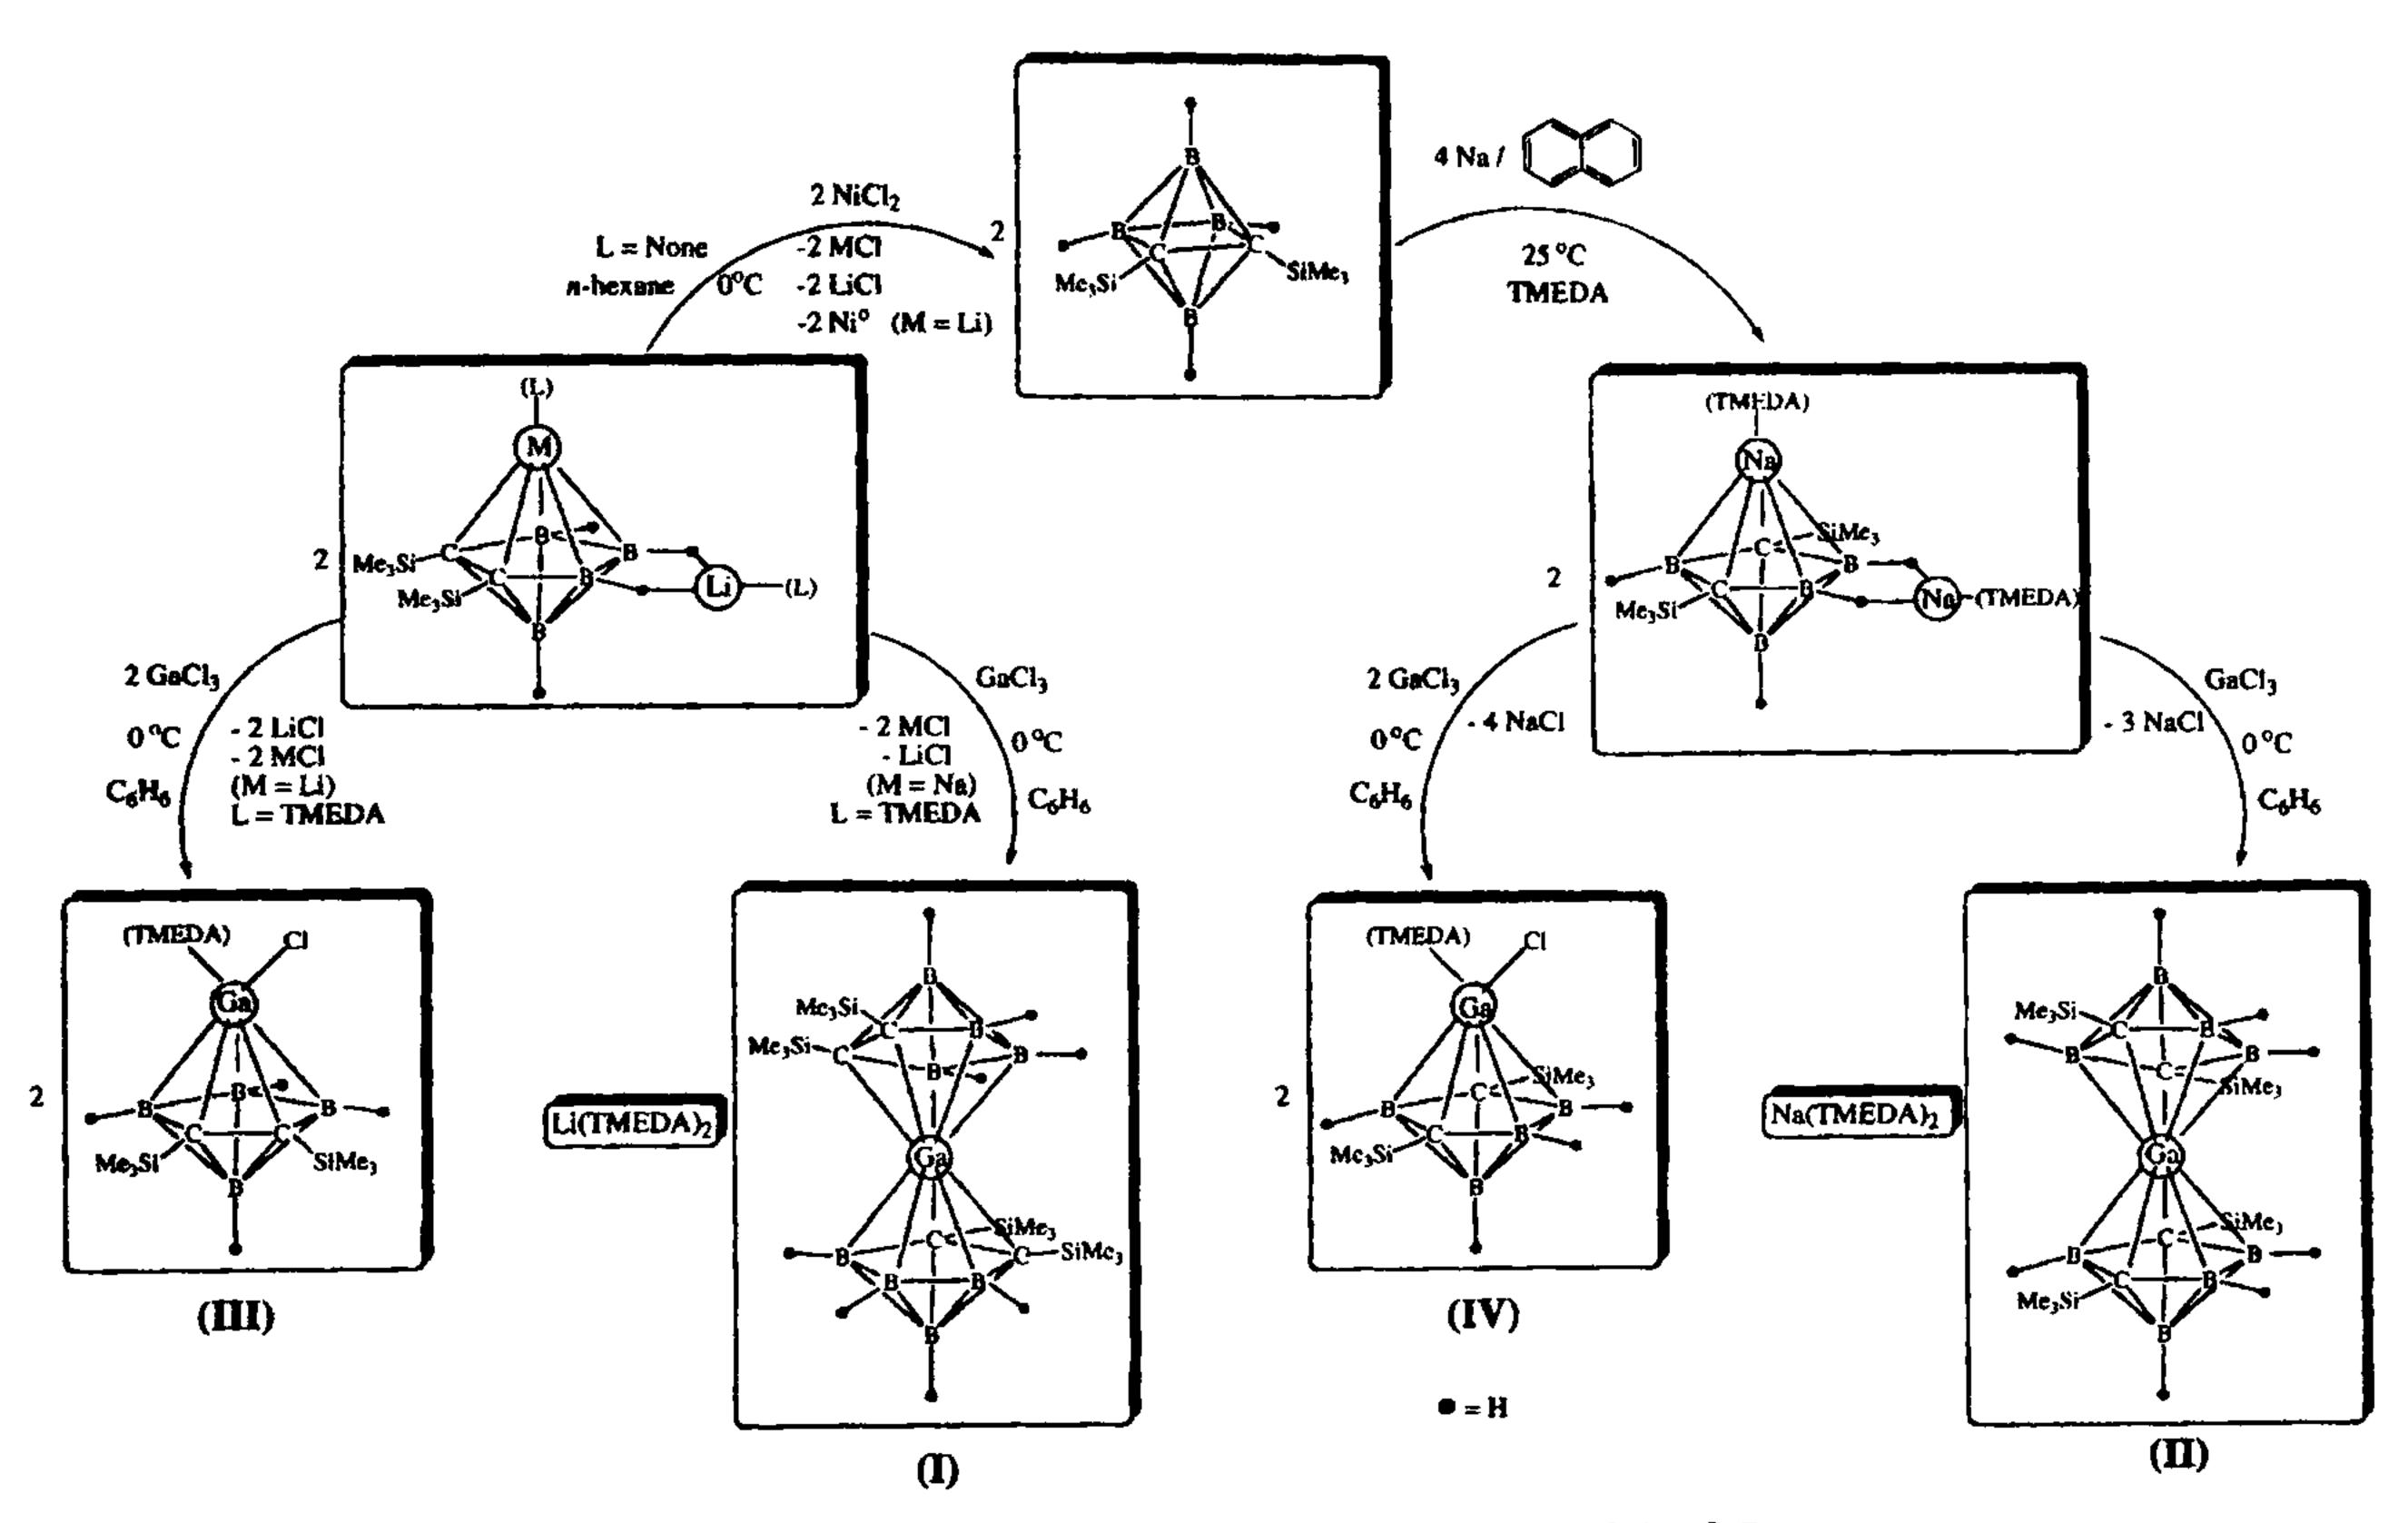

Figure 9. Electron-precise heterocyclic ring.

apart'  $C_2B_4$ -carborane systems<sup>2(a)</sup>. These reports collectively demonstrated that the reactive part of the molecule is the apical gallium metal that acts as a Lewis acid site by making donor-acceptor complexes with 2,2'-bipyridine, 2,2'-bipyrimidine, and 2,2':6',2''-terpyridine. In each complex, the apical gallium is slip-distorted away from the cage carbons and, in the case of the 1,2,4-Ga(CR)<sub>2</sub>B<sub>4</sub>H<sub>4</sub>, the metal is away from the unique boron above the  $C_2B_3$  bonding face. Nonetheless,

Scheme 4. Syntheses of half- and full-sandwich gallacarboranes of the C2B4-cage systems.

these reports exemplified the pattern of reactivities that are not only inherent in these half-sandwich tbutylgallacarboranes, but also identical to those of the other group 13 and group 14 half-sandwich metallacarboranes in both the  $C_2B_4$  and  $C_2B_9$  carborane systems<sup>2(a)</sup>. It is of interest to note the divergence of the reaction products in the C<sub>2</sub>B<sub>4</sub> and C<sub>2</sub>B<sub>9</sub> cage systems. The former cage system containing only half-sandwich complexes, while the latter system yields only the full-sandwich metallacarboranes. This is probably due to the nature of the metal reagent used in the syntheses, rather than a difference in bonding preferences in the two cage systems. The half-sandwich complexes were obtained from metal alkyl reagents<sup>2(a)</sup>, such as  $Ga(CH_3)_3$ ,  $[(t-C_4H_9)-$ GaCl<sub>2</sub>]<sub>2</sub>, or (Me<sub>2</sub>CH)InI<sub>2</sub>, while the full-sandwich complex resulted when GaCl<sub>3</sub> as the metallating agent<sup>22</sup>. When GaCl<sub>3</sub> is substituted for [(t-C<sub>4</sub>H<sub>9</sub>)GaCl<sub>2</sub>]<sub>2</sub> in the reaction with the dilithium complexed [2,n-(SiMe<sub>3</sub>)<sub>2</sub>-2,n-C<sub>2</sub>B<sub>4</sub>H<sub>4</sub>]<sup>2-</sup> dianion in 1:2 stoichiometry in TMEDA, the full-sandwich compound, [commo-1,1'-Ga(2,n- $(SiMe_3)_2-1,2,n-GaC_2B_4H_4)_2$ , (n = 3, 4) was obtained (see Scheme 4 and Figures 10 and 11), while the same reaction in 1:1 stoichiometry resulted, in high yields, in the formation of a half-sandwich chlorogallacarborane,  $closo-1-(TMEDA)-1-(C1)-2,n-(SiMe_3)_2-1,2,n-GaC_2B_4H_4$ (Figure 12) (ref. 23), which was further converted to the corresponding closo-gallacarborane hydride (Figure 13) and alkyl derivatives<sup>24</sup>. The structures of the gallacarboranes show that the gallium atoms are not equally

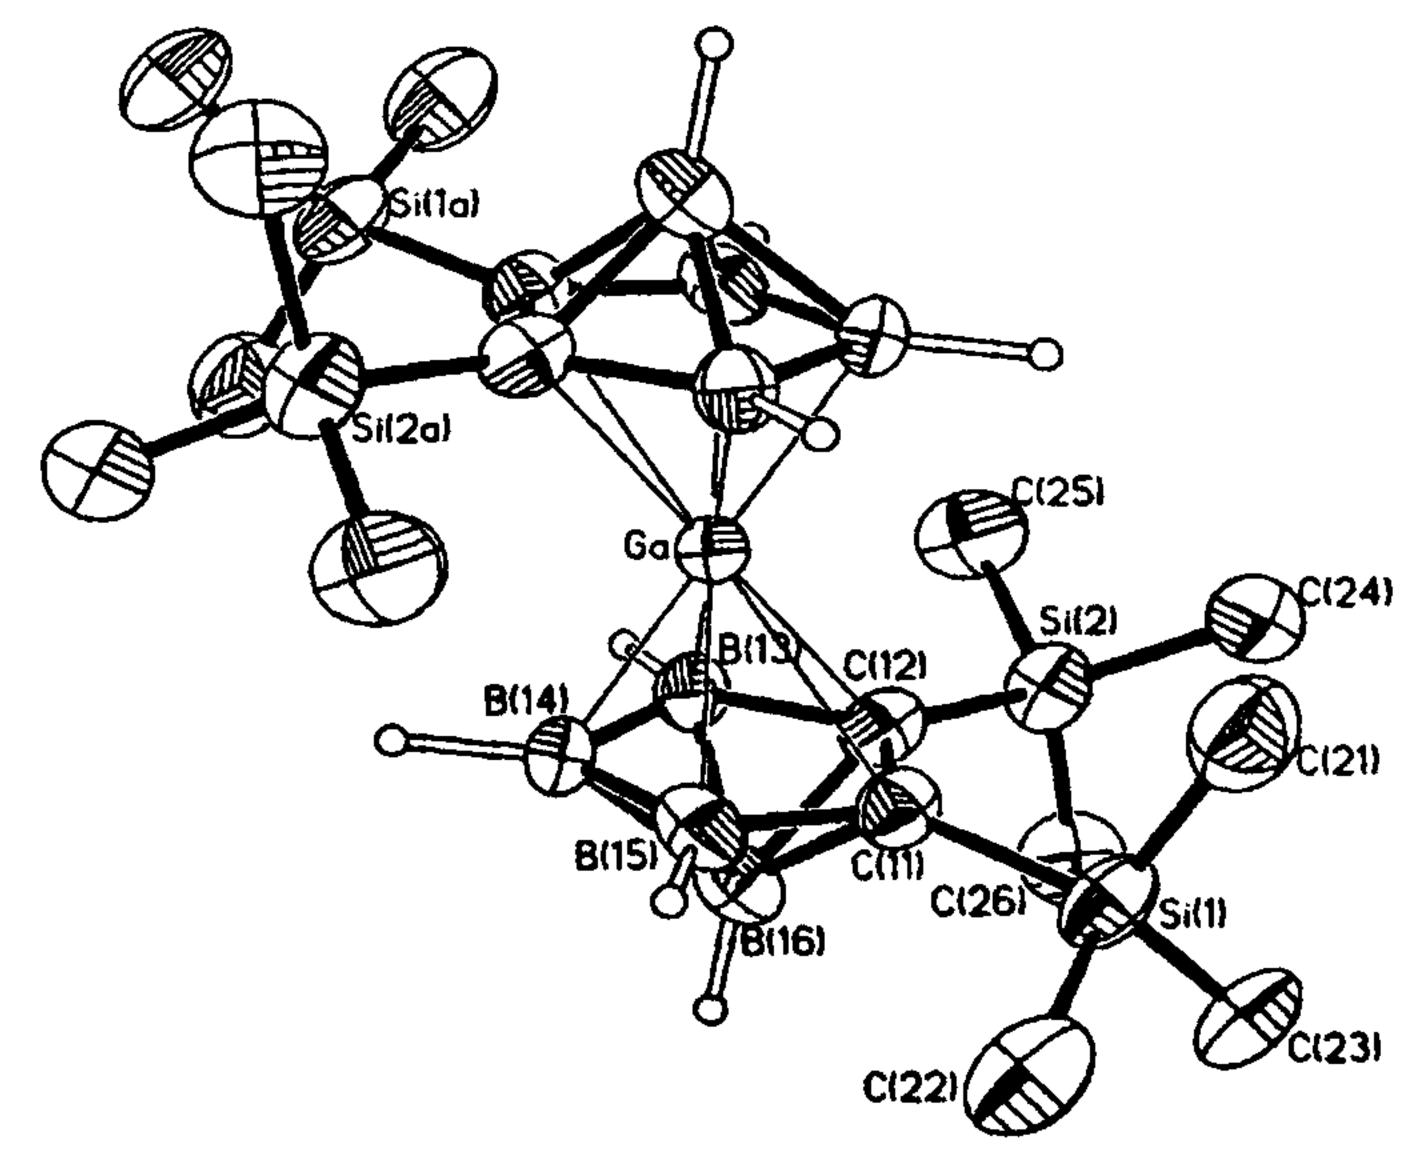

Figure 10. Crystal structure of the anionic 'c-adjacent' commogallacarborane.

bonded to the atoms in the  $C_2B_3$  faces of the carboranes but are slipped toward the more boron-rich sides of the faces. Slippages in the full-sandwich gallacarboranes are such that maximum differences in the  $Ga-C_2B_3$  distances were 0.34 Å in Figure 10 and 0.45 Å in the other isomer shown in Figure 11. These distortions were much larger in the half-sandwich complexes such that the carboranes are better described as being  $\eta^3$  or  $\eta^2$ -bonded to the apical gallium metal<sup>23</sup>.

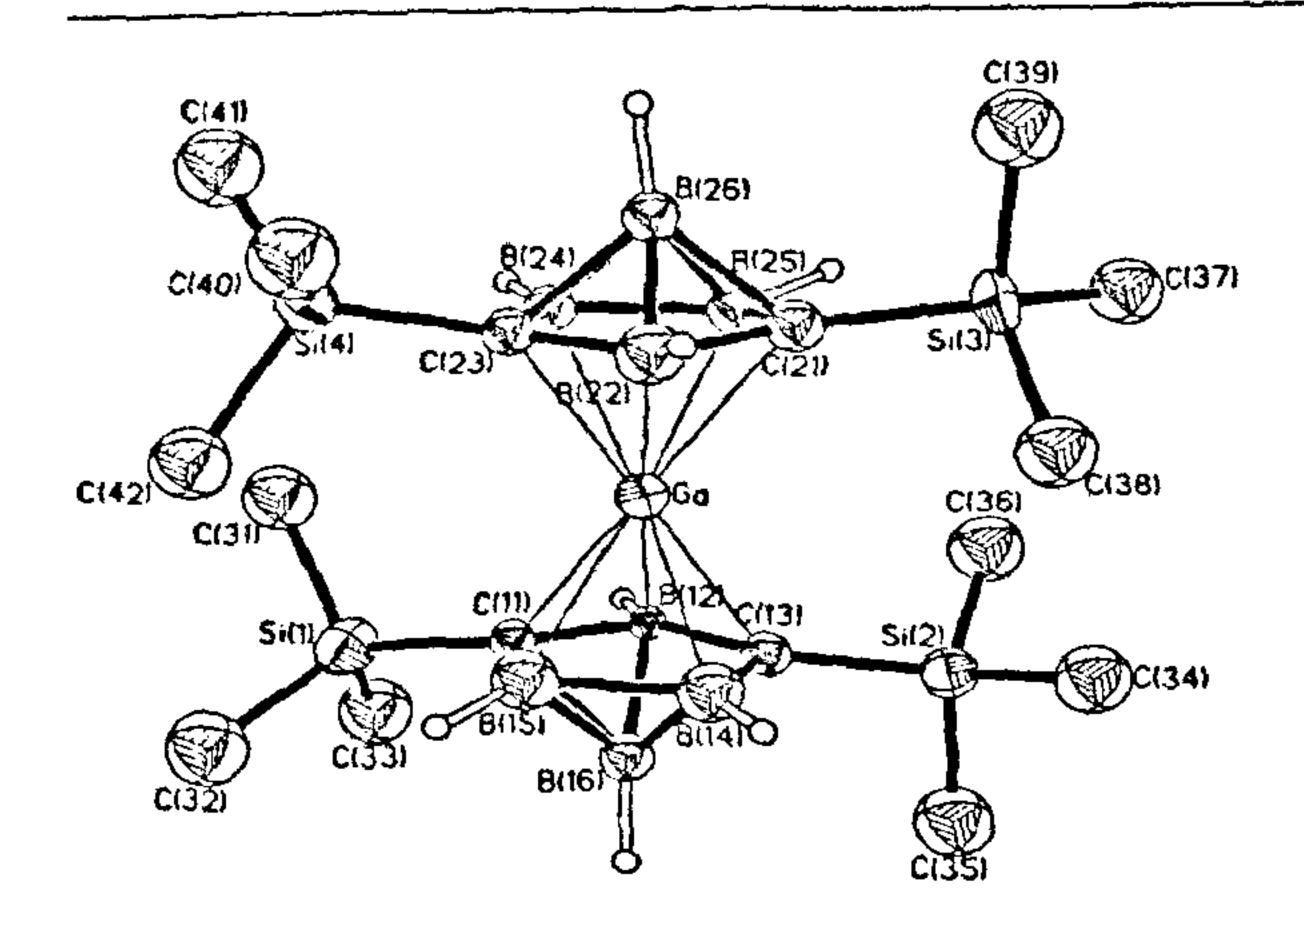

Figure 11. Crystal structure of the 'c-apart' anionic commogallacarborane.

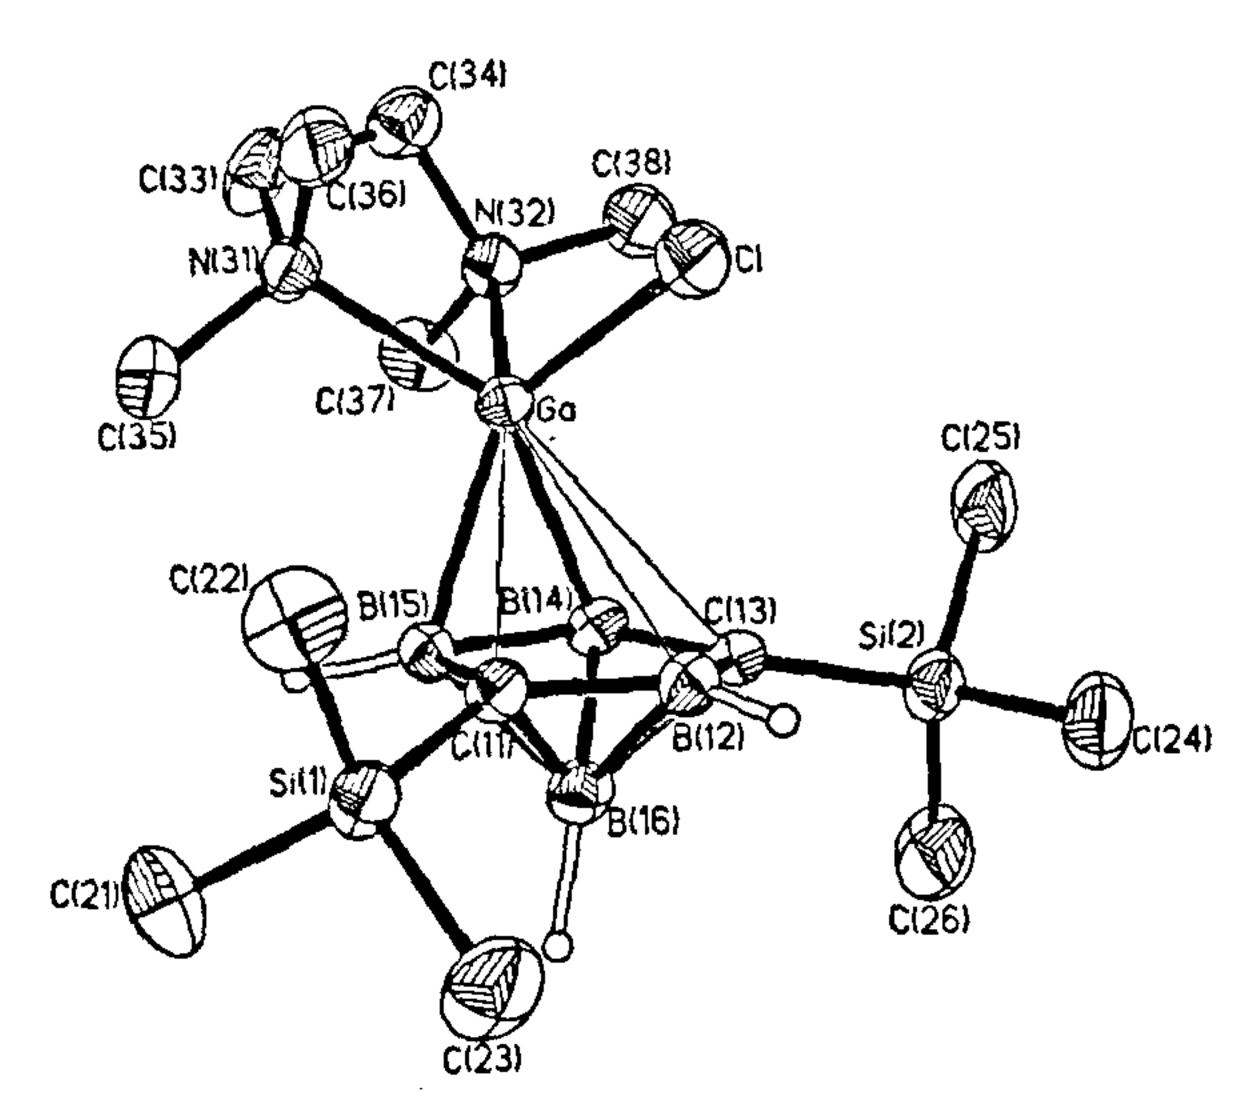

Figure 12. Crystal structure of the 'c-apart' closo-chlorogallacarborane.

A surprising formation of Ga(II)-Ga(II)-linked digallacarborane was observed in the reaction of [Ga(t-Bu)Cl<sub>2</sub>]<sub>2</sub> with the disodium compound of the 'C-apart' carborane dianion, in 1:2 stoichiometry<sup>25</sup>. The two major products were half-sandwich gallacarborane and a novel digallacarborane, which could be separated by fractional distillation and sublimation. The crystal structure of the digallacarborane (Figure 14) exhibits the shortest Ga-Ga bond distances known to date. All evidence shows that there is no multiple metal-metal bonding. While the mechanism for the formation of this species is not known, the dependence on the nature of the group I metal in the precursor indicates that this compound is probably not the result of a simple elimination of t-Bu groups during the isolation of the halfsandwich gallacarborane via vacuum distillation<sup>25</sup>.

## Reactivity of $C_2B_4$ -carboranes with group 14 elements

Research in the area of group 14 metallacarboranes has been quite active in recent years 1(b,c),2(a). All elements in

CURRENT SCIENCE, VOL. 78, NO. 4, 25 FEBRUARY 2000

Scheme 5. Syntheses of mixed valence germacarboranes and their adducts.

that group have been inserted into carborane cages and a wealth of structural information is available on a number of half-sandwich, closo-carboranes of germanium, tin and lead as well as the full-sandwich, commo-complexes of silicon, germanium and tin<sup>2(a)</sup>. These studies show that a definite structure-oxidation state relationship exists in these systems; in the closo-complexes the capping group 14 elements are in formal +2 oxidation states, while the commo-complexes contain the elements in their +4 states. The coordination chemistry of closo-M<sup>u</sup>C<sub>2</sub>B<sub>4</sub> metallacarboranes has also been investigated and the structures of the resulting donor-acceptor complexes involving Lewis bases such as 2,2'-bipyridine (C<sub>10</sub>H<sub>8</sub>N<sub>2</sub>), 2,2'-bipyrimidine (C<sub>8</sub>H<sub>6</sub>N<sub>4</sub>), (ferrocenylmethyl)-N,N-dimethylamine,  $[(\eta^5-C_5H_5)-Fe(\eta^5-C_5H_4CH_2)]$ (Me)<sub>2</sub>N)], and 2,2':6',2"-terpyridine ( $C_{15}H_{11}N_3$ ) have been reported<sup>1(c),2(a)</sup>. The structures of these adducts show that, despite having a 'lone pair' of electrons, the group 14 element acts as a Lewis acid and bonds to the base. Coordination by the base leads to a distortion of the MC<sub>2</sub>B<sub>4</sub> cage in that the metal atom is dislocated, or slipped toward the boron side of the C2B3 face of the carborane ligand; in all cases the base molecules are oriented opposite the cage carbons. These results raised the general question as to what would be the outcome of

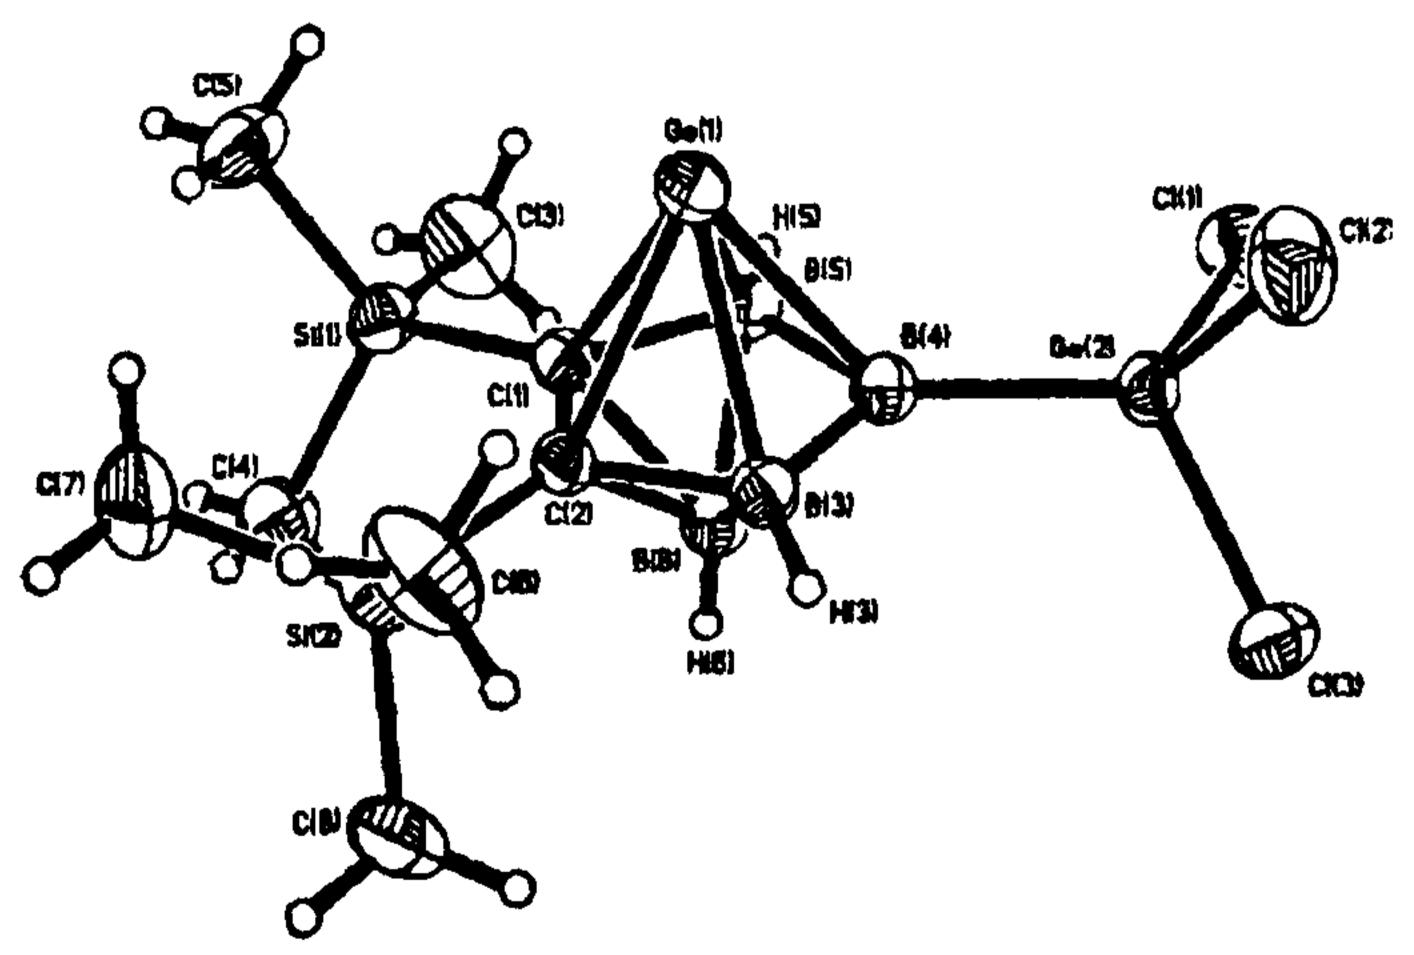

Figure 15. Structure of the mixed valence closo-germagarborane.

the reactions between Lewis bases and metallacarboranes possessing two potential acid sites, an M<sup>II</sup> and an M<sup>IV</sup> metals. In an effort to ascertain which metal atom would be the preferred acid site and to obtain more information regarding the structure, bonding and reactivity pattern of the new class of mixed-valence metallacarboranes, we have synthesized several B-GeCl<sub>3</sub>-

substituted closo-germacarboranes, [1-Ge-2-(SiMe<sub>3</sub>)-3-(R)-5-(GeCl<sub>1</sub>)-2.3-C<sub>2</sub>B<sub>4</sub>H<sub>3</sub>] (R = SiMe<sub>3</sub>, Me and H), as outlined in Scheme 5. A representative structure, when R = SiMe<sub>1</sub>, is shown in Figure 15 (ref. 26). This scheme summarizes the reactions leading to the formation of the mixed valence germacarboranes. No neutral GeCl<sub>3</sub> substituted carborane was found in the reaction products, indicating that the initial step in the reaction sequence is the reductive insertion of germanium to form a closo-germacarborane, which then reacts with a second GeCl<sub>4</sub> molecule to give the mixed valence complex and HCl. Such a substitution is not unreasonable from an energy standpoint. For example, ab initio molecular orbital calculations at the B3LYP/6-31G\* level showed that  $\Delta E$  for eq. (1) would be -20.83 kJ/mol<sup>26(b)</sup>.

$$closo$$
-1,2,3-GeC<sub>2</sub>B<sub>4</sub>H<sub>6</sub> + GeCl<sub>4</sub> → 5-GeCl<sub>3</sub>-1,2,3-GeC<sub>2</sub>B<sub>4</sub>H<sub>5</sub> + HCl. (1)

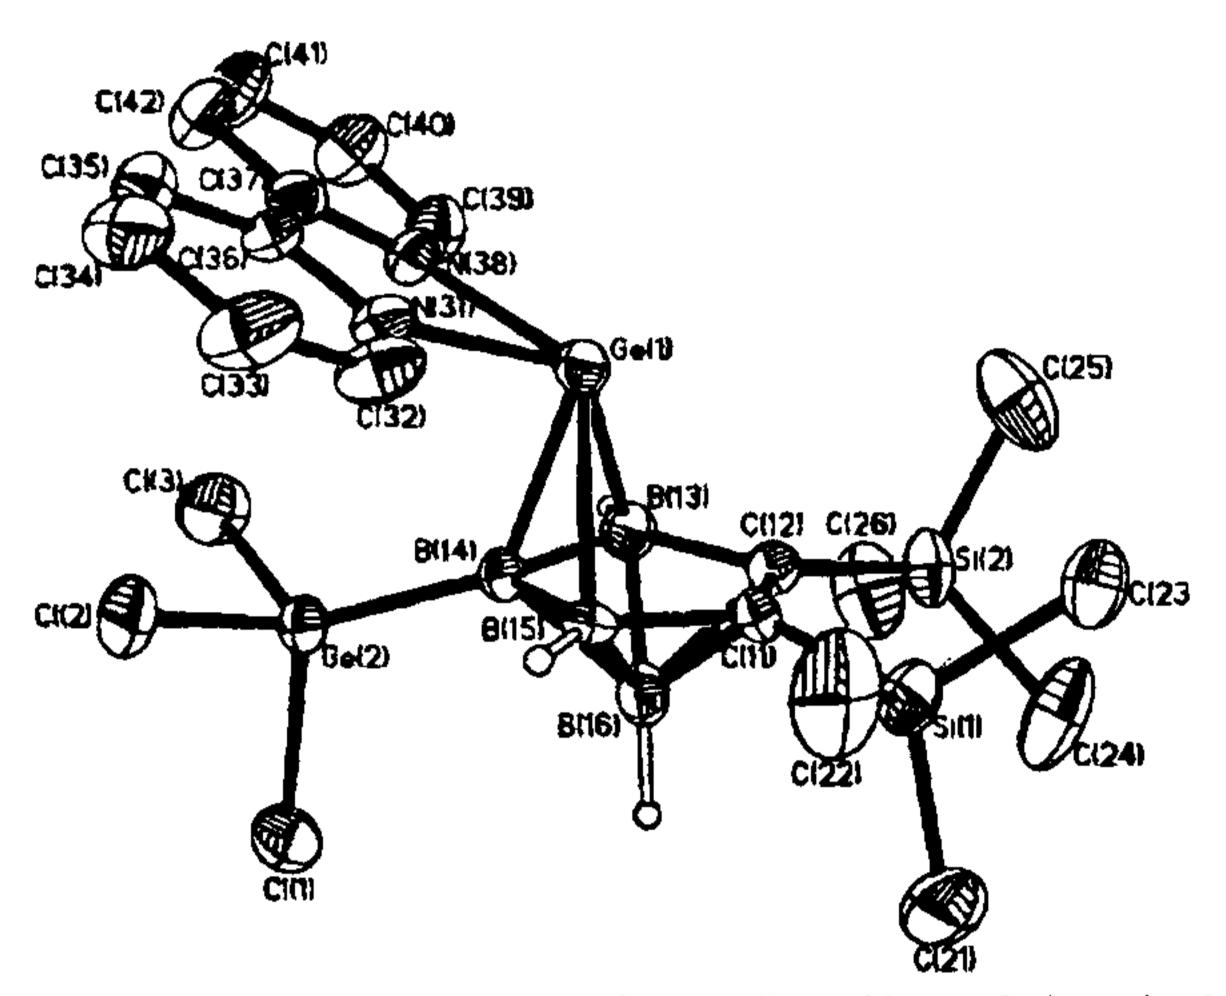

Figure 16. Structure of the 2,2'-bipyridine-adduct of the mixed valence germacarborane.

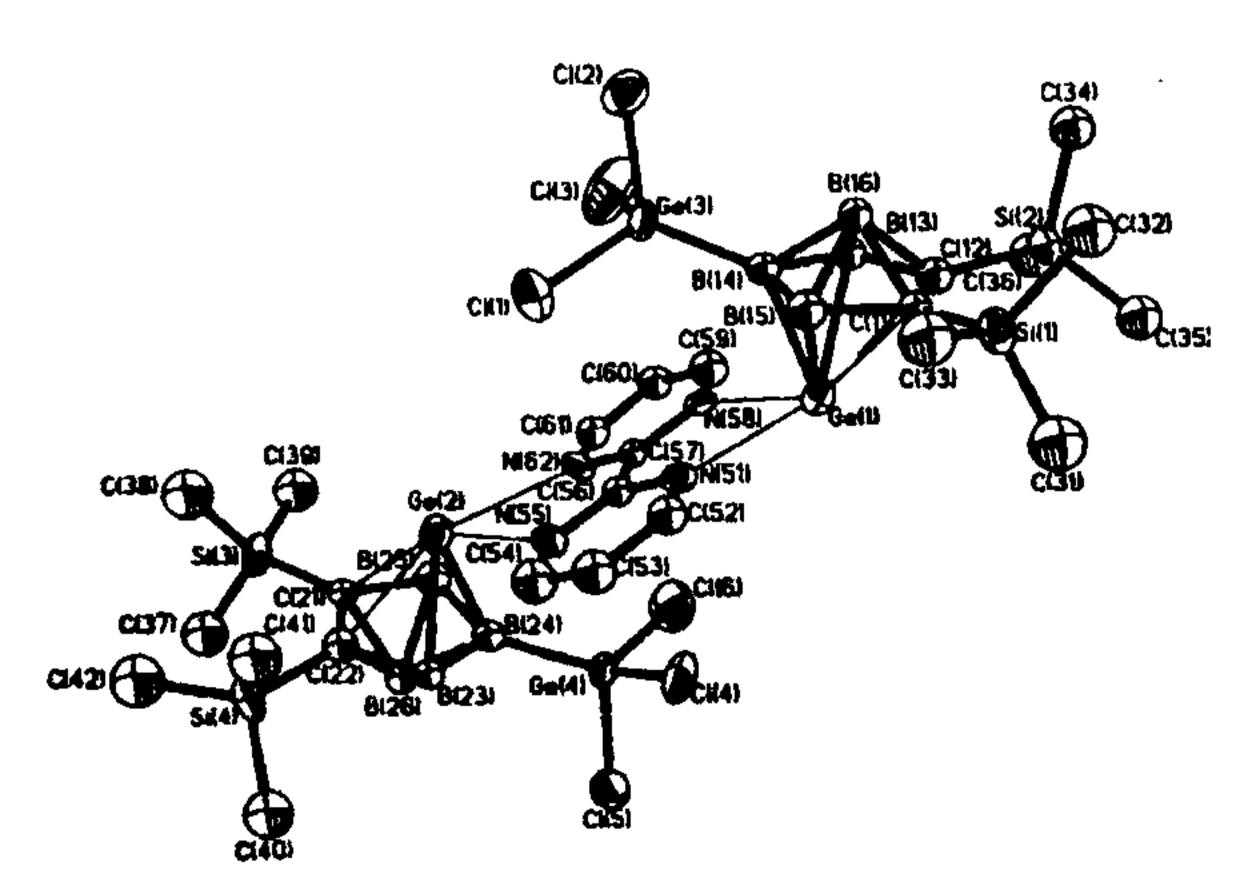

Figure 17. Crystal structure of the 2,2'-bipyrimidine adduct of a mixed valence closo-germacarborane complex.

Although this value is only approximate and is for the gas phase, it does indicate that the substitution of a GeCl<sub>3</sub> unit for a terminal H would be an energetically favourable reaction.

There are two Lewis acid sites in closogermacarboranes (see Figure 15), the apical Ge(II) and the exopolyhedral Ge(IV). While one would qualitatively expect the higher oxidation state Ge to be the site for base coordination, just the opposite was found with all Lewis bases studied (2,2'-bipyridine, 2,2'-bipyrimidine and 2,2':6':2''-terpyridine) in which the donor N atoms bond exclusively with the apical Ge(II) (see Figures 16 and 17, for example)<sup>26(b)</sup>. It is of interest to note that the reaction of the underivatized germacarboranes with the bis(bidentate) ligand  $C_8H_6N_4$  resulted in 1:1 donor-acceptor complexes 1(c),2(a), rather than the bridged compound shown in Figure 17 (ref. 26(b)). In this regard, the mixed valence closo-germacarboranes are more analogous to the stannacarboranes which react with C<sub>8</sub>H<sub>6</sub>N<sub>4</sub> to give bridged 2:1 complexes <sup>1(c),2(a)</sup>. Thus, even though two germanium atoms are present, no evidence has been found to indicate that the Ge(IV) atoms in these compounds act as Lewis acid sites. An inspection of the LUMO and LUMO + 1 molecular orbitals obtained from ab initio calculations at the HF/3-21G\* level of theory shows localization only on the apical Ge(II) and carborane cage. Therefore, from frontier orbital considerations one would predict that the lower valence apical germanium would be the preferred reaction site for a nucleophile. It seems that the Ge(IV) atoms in the mixed valence closo-germacarboranes have their valences well-satisfied through bonding to the three chlorine atoms and the unique borons; even strong nucleophiles displace, rather than disrupt, the GeCl<sub>3</sub> moiety<sup>26(b)</sup>.
