25 **Abstract**

26

27 Wind power growth makes it essential to simulate weather variability and its impacts on the
28 electricity-grid. Low-probability, high-impact, weather events , such as a wind-drought are
29 important but difficult to identify based on limited historical datasets. A stochastic weather
30 generator, Imperial College Weather Generator (IMAGE), is applied to identify extreme
31 events through long-period simulations. IMAGE captures mean, spatial-correlation, and
32 seasonality in wind speed and estimates return periods of extreme wind-events over India.
33 Simulations show that when Rajasthan experiences wind-drought, Southern India continues
34 to have wind and vice versa. Regional grid-scale wind-droughts could be avoided if grids are
35 strongly interconnected across India.

36

37 **Keywords: Decarbonization, Wind Energy, Stochastic Weather Generators, Wind Drought,**
38 **Grid Interconnections**

39

40 **1: Introduction**

41

42 As part of its progress toward decarbonization, India has plans to increase the share of
43 renewable energy (wind and solar) in its electricity system¹. Decarbonization or reduction in
44 fossil fuel sources of energy is also important for reducing air pollution^{2,3}. In an electricity
45 grid with a large share of renewables, weather variability would impact not only demand but
46 also the supply of electricity, making it necessary to simulate weather variability and its
47 impacts on the power system⁴. In addition to normal weather variability, low probability
48 high impact weather events can have an adverse impact on grid stability by creating large
49 deficits in electricity generation. Successfully managing steep ramps in generation output, as

50 well as a range of demands or power generations as a result of weather variability over
51 different time scales is crucially important for reliable operation of power systems ⁴.
52
53 Wind speed variability often arises from large-scale weather patterns ⁵, giving rise to
54 correlated extreme excesses or deficits in wind generation. The statistics of such extreme
55 events typically cannot be estimated from the instrumental record, because their relative short
56 duration does not contain many realizations of such events. Nevertheless, such extreme
57 weather events can be the result of underlying structure, such as the covariance in wind-speed
58 between different pairs of locations. Stochastic weather generators can help in identifying
59 such extremes, especially when they arise from statistics that can be estimated from shorter
60 instrumental datasets.
61
62 Sparks et al. (2018) ⁶ presented the Imperial College Weather Generator (IMAGE), a novel
63 multi-site multivariate stochastic weather generator that can capture various extreme events,
64 including heatwaves and cold spells, droughts, and excess rainfall. Stochastic weather
65 generators typically produce single-site time series of an arbitrary length of meteorological
66 variables, while preserving statistics of the input data, which are obtained from historical
67 observations, reanalyses, or models. In their simplest form, weather generators produce
68 synthetic time series for a single weather variable at a single location. However, for many
69 applications, the geographic area considered is so large that weather variables, such as wind,
70 can vary significantly over the domain. In such situations time series at multiple sites are
71 desirable. The production of realistic synthetic weather data, in this case, requires the
72 preservation of spatiotemporal correlation between sites, increasing the complexity of the
73 problem significantly, in proportion to the number of pairs of sites. Additionally, for many
74 applications, time series of multiple, correlated weather variables are needed. The weather

75 generator IMAGE is designed to be used to assess the risk of events for which the spatial
76 distribution of weather variables is essential, such as rainfall anomalies over several months
77 over a large watershed or heatwaves affecting several regions of a country over a period of a
78 few days ⁶. This model uses multi-variate autoregressive modelling. Besides precipitation,
79 other meteorological variables such as minimum and maximum daily temperature, solar
80 radiation, humidity, and wind speed have been generally modelled using multi-variate
81 autoregressive models ⁷. Here we apply IMAGE for the first time to data from outside
82 Europe and explore the risk of wind droughts across India.

83

84 **2: IMAGE model description**

85

86 We use an improved version of the IMAGE model described by Sparks et al (2018) ⁶. We
87 include only a brief description of the model here, presenting a more detailed explanation of
88 the modifications.

89

90 All variables in IMAGE are modelled as latent Gaussian variables. At the start of simulation
91 each variable is transformed using a normal quantile transformation such that it has a normal
92 distribution. These transforms are performed separately for each month to allow for changes
93 in the distribution from month to month. Once transformed, an autoregressive lag-1 model of
94 the form

$$95 \quad y_s(t) = c_s + \alpha_s y_s(t-1) + \epsilon_s \quad (1)$$

96 is fitted separately to each month of input data for each variable at each site, where c_s is a
97 constant, α_s is referred to as the memory parameter and ϵ_s is a noise term. These three
98 parameters are each, in turn, modelled as latent Gaussian variables and are transformed such

99 that each parameter has a normal distribution for each variable at each site for each calendar
100 month.

101

102 Synthetic time series are simulated for each variable at each site by first generating correlated
103 values of c_s and α_s for each month by sampling from a multivariate normal distribution. This
104 process requires the decomposition of the covariance matrix of the autoregressive parameters,
105 Σ , to a matrix C such that $CC^T = \Sigma$. In Sparks et al (2018) ⁶ this is achieved using empirical
106 orthogonal function decomposition, however, in this study we instead use Cholesky
107 decomposition, which produces the same results but is computationally faster. In general, Σ
108 may not be positive semi-definite, which is required when sampling from the multivariate
109 normal distribution, and therefore the nearest positive semi-definite matrix to Σ is computed
110 using the method of Higham (1988) ⁸. Parameters are generated simultaneously for all twelve
111 months in one simulated year, such that correlations between months in the same year are
112 accurately simulated, as well as spatial correlation between sites. As well as simulating
113 monthly parameters, the noise terms ϵ_s are simulated daily for each variable at each site, once
114 again by sampling from a multivariate normal distribution. Daily values for each variable at
115 each site can then be simulated using Eq. (1).

116

117 After simulation, variables are transformed back to their original distributions using an
118 inverse normal quantile transformation. The pairwise Pearson's correlation coefficient of
119 time series of variables at different sites are calculated for the simulated data and compared to
120 the correlation coefficients of the input data. As described in Sparks et al (2018) ⁶, the
121 original version of IMAGE tended to systematically under-simulate the observed spatial
122 correlations. IMAGE has been modified to mitigate this issue using an iterative method.

123 Once one simulation run is complete, the covariance matrix used to generate the daily noise
124 terms, ϵ_s , is adjusted by applying a correction term equal to the difference between the
125 observed correlation and the simulated correlation for each pair of sites. The simulation of ϵ_s
126 is then re-run and this cycle is iterated until a satisfactorily small error in the simulated
127 pairwise correlations is achieved. We found that ten iterations were sufficient to reach
128 approximate convergence.

129

130 **3: Data used and Methodology**

131

132 The analysis of this paper was based on horizontal wind speed at 100 m over surface from
133 ERA5 reanalysis products by the European Centre for Medium-Range Weather Forecasts
134 (ERA5) ⁹ for 41 years (1979 - 2019) over the Indian region. We choose 100 m above surface
135 because the hub heights of various onshore wind turbines lie roughly at that level. The spatial
136 resolution of the reanalysis dataset is 0.25 x 0.25 degrees, and the temporal resolution is
137 hourly. In-situ, hourly 100 m wind measurement data of 40 weather stations from National
138 Institute of Wind Energy (NIWE) is compared with ERA5 data to check if ERA5 could
139 capture the overall wind speed pattern.

140

141 The methodology of the paper is the following. First, we test if ERA5 could capture the
142 overall pattern of observed wind speed over India (from NIWE measurement for 40 locations
143 - in Figure 1, purple dots). However, we note that the goal of the paper is to present and
144 highlight the value of the stochastic weather generator to model wind-power variability. The
145 IMAGE model which is presented here can be used with different sources of data input, and
146 we have chosen the best physically consistent gridded data set available to us. The input data

147 can change , but the tool presented here remains applicable to a variety of weather variables,
148 depending on the context.

149

150 Next, the IMAGE weather generator was validated for wind speeds over the Indian region.

151 The model was simulated for 40 locations (in Figure 1, purple dots) over wind-rich regions

152 located in western and southern India for daily wind speed of 4100 years. The output of 4100

153 years of IMAGE simulation for each of these locations is segregated into 100 ensemble

154 members, each of 41 years length (i.e., same length as input data). For each of these ensemble

155 members, the 41 years' daily wind speed time-series was compared with the corresponding

156 time-series in the ERA5 input dataset. The parameters chosen for comparison are the yearly

157 mean of the daily wind speed, seasonal variation of the monthly mean wind speed, and spatial

158 correlation of wind speed. Three locations are used to illustrate the validation of seasonal

159 patterns (Figure 1, green triangles), from three different high wind resource regions in India:

160 Dhanuskodi in the off-shore region near south India, and two onshore locations in Box A

161 (Rajasthan) and Box B (South India). We also examine if the wind speed simulated by

162 IMAGE could preserve the Weibull distribution of wind speeds.

163

164 As part of validation of the simulations from IMAGE, we also examine whether these capture

165 the low probability extreme events of high and low wind speed. This analysis compares the

166 return periods of various wind speed events from the ERA5 reanalysis with IMAGE

167 simulations. This validation is done for two high wind-resource regions within Rajasthan

168 (Box A) and South India (Box B) (Figure 1, brown squares).

169

170 Following the validation as described above, IMAGE has been used to simulate 1000 years of

171 wind speed over India based on the ERA5 reanalysis as input data. The ERA5 data has been

172 upscaled to 1 x 1 degree resolution, prior to serving as input to IMAGE. Based on the
173 IMAGE simulations, we estimate the probability of low wind (“wind drought”) over different
174 regions and all-India. We estimate the fraction of days for which the average wind speed is
175 below 3 m/s all over India, given one of the wind-rich regions, Box A (Rajasthan) or Box B
176 (South India) has an average daily wind speed below 3 m/s. The 3 m/s threshold is
177 considered because as most of the turbines have a “cut in” speed of 3 m/s, i.e., the wind speed
178 beyond which the turbines start producing electricity.

179

180 Finally, through a case study, we illustrate the benefits of having grid-connected wind plants
181 located in different regions, as compared to the absence of any interconnection between
182 regional grids. These benefits are assessed from the perspective of “wind drought” or “no
183 generation days” based on the IMAGE simulation of 1000 years. We simulate wind turbines
184 in four sets of locations from Box A and Box B for the case study.

185

186 Set 1: One grid having maximum mean wind speed in Box A and another neighbouring grid

187 Set 2: One grid with maximum mean wind speed in Box B and another neighbouring grid

188 Set 3: Grids with maximum mean wind speed in both the boxes

189 Set 4: Grids with second highest mean wind speed in both the boxes

190

191 We simulate one 2.1 MW wind turbine at each location. The manufacturer’s power curve of

192 Suzlon S.88-2100¹⁰ model turbine with a rated power output of 2.1 MW is used for

193 converting the wind speed to the wind generation. A lookup table created based on the

194 normalised power curve is used for converting the IMAGE simulated wind speed to wind

195 generation. Due to normalisation the rated generation from the turbine is indicated as 1.

196 Hence, wind generation for any given wind speed can be interpreted as fraction of the rated
197 generation obtained at that wind speed.

198

199 To compare the benefits of having wind farms located in the different sets of locations, we
200 estimate the fraction of days in 1000 years for which there was no generation from the
201 individual plants as well as no generation from the combination of the two simulated wind-
202 power plants. Improvement in the fraction of “no generation” days can be used as a potential
203 parameter to assess the benefits of aggregating wind plants from different regions.

204

205 Next, we assess the robustness of this parameter (fraction of “no generation” days). Twenty
206 grids were selected from Box A and Box B, which have higher average daily wind speed
207 compared to other grids. Equal number of grids (10) were selected from each boxes. We
208 simulate all possible combinations of 4 grids that can be selected from among these 20 grids.
209 One wind turbine is simulated at each location. We estimate the reduction in percentage of
210 “no generation” days in the aggregate generation for each combination. The reduction values
211 are estimated based on Equation 2.

$$212 \quad R = \frac{\sum_1^4 f_i}{4} - f_c \quad (2)$$

213 Where f_i and f_c are fraction of zero generation days estimated for individual and combined
214 generations from simulated wind plants respectively. R is the absolute value of reduction in
215 fraction of zero generation days achieved by aggregation.

216

217 **4: Model validation**

218

219 **4.1 ERA5 reanalysis dataset and observation**

220 Before using ERA5 as input for IMAGE, we check if ERA5 could capture the wind speed
221 over India. Figure 2A compares the daily mean wind speed for 40 NIWE wind monitoring
222 stations in wind rich regions of India with ERA5. There is some underestimation of point
223 observation of wind speed in ERA5, which might result from spatial averaging of wind speed
224 in the gridded dataset. ERA5 captures the spatial pattern of daily mean wind speed with
225 moderate accuracy (correlation coefficient is 0.58 with p-value ≈ 0). However, it is important
226 to note that the focus of the paper is to present and highlight the value of the stochastic
227 weather generator to model wind-power variability, and the tool presented here can be
228 applied to a variety of weather variables.

229

230 ERA5 outperforms ERA-Interim and MERRA-2 consistently across many parts of the world
231 and so this reanalysis is recommended for local wind power studies¹¹. Molina et al (2021)¹²
232 show that ERA5 is able to reproduce the wind speed spectrum over Europe. The authors
233 note¹² that despite shortcomings ERA5 provides a regular spatial and temporal wind
234 distribution that is important for renewable energy studies. Belmonte and Stoffelen (2019)¹³
235 analyze differences between ERA-Interim and ERA5 surface winds fields relative to
236 Advanced Scatterometer (ASCAT) ocean vector wind observations and note that ERA5
237 performs better than ERA-Interim in terms of mean and transient wind errors.

238

239 Figure 2B compares observed and ERA5 monthly wind speed patterns for a NIWE wind
240 monitoring station, Devereddyipalli; The red dot indicates the monthly median wind speed

241 from 41 years of ERA5, the vertical line shows the distribution; Although, ERA5
242 underestimates the wind speed, the seasonal pattern is captured accurately.

243

244 **4.2 Mean wind speed, seasonal pattern and spatial correlation**

245

246 Simulations from IMAGE are able to represent the mean wind speed very well over India.

247 The validation IMAGE simulations are performed for 40 locations each having 100 ensemble

248 members that are as long as the input data, i.e., 41 years. A linear regression between the

249 mean wind speed from the input data and IMAGE simulations was performed, and the bias is

250 small, and the R square value is 0.99. This comparison is made in Figure 3A, where the dots

251 show the median values and the vertical lines indicate the distribution of the ensemble

252 members for each location. This distribution is narrow, indicating that each of the ensemble

253 members approximate the mean wind-speed closely.

254

255 Next, we assess if IMAGE simulations could represent the spatial correlation of wind speed

256 between various locations. We consider Dhanuskodi as a reference location, and compare the

257 spatial correlation coefficient between daily wind speed for ERA5 input data and IMAGE

258 simulations between Dhanuskodi and each of the other 40 locations (Figure 3B). Each of the

259 dots in Figure 3B indicates the median of the 100 ensemble members from simulation plotted

260 against the ERA5 value, between Dhanuskodi and one other location. The vertical lines show

261 the distribution among the 100 ensemble members of the correlation coefficient, for each

262 pair. These results demonstrate that IMAGE is able to successfully represent the spatial

263 correlation of wind speed in its simulations. The R square value of a linear regression

264 between the correlation coefficients of input and simulated output is 0.99, and the bias is

265 small.

266

267 Much of India experiences high wind speed during the summer monsoon months (JJAS –
268 June, July, August and September). Figure 3C shows seasonal variation of wind speed at
269 three locations indicated in Figure 1: Dhanuskodi, Devereddyipalli and Bassi. For each
270 location, the solid lines indicate the ERA5 inputs while the dashed lines indicate distributions
271 from the IMAGE simulations. The crosses and the triangles show the ensemble medians of
272 the monthly wind speed from ERA5 and IMAGE simulations respectively, and the vertical
273 bars indicate the distribution in each case. The IMAGE simulation captures this seasonal
274 variation quite well.

275

276 **4.3 Wind speed distribution pattern**

277

278 Wind speeds are expected to follow a Weibull distribution¹⁴. Figure 4 compares the
279 probability distribution plot of the ERA5 input data for 41 years and IMAGE simulated wind
280 speed for 4100 years (4100 x 365 data points) for two locations, Gudaparihar and Bassi. The
281 red lines show the Weibull distribution fits with appropriate shape and scale factor for the
282 distributions. This shows that IMAGE simulations could preserve the wind speed
283 distribution.

284

285 **4.2 Return Periods**

286

287 We estimate the return periods of different values of wind speed for both the wind rich
288 regions (Box A and Box B) shown in Figure 1. Figure 5A and Figure 5B show the return
289 periods of different values of spatially averaged wind speed in Box A (Rajasthan) and box B
290 (South India). The red dots show the median of the return period based on ERA5 input data

291 (41 years) while the blue dots show the simulated return period in 1000 years. Corresponding
292 ranges are also indicated by the horizontal bars. The results show that the ERA5 dataset does
293 not contain many instances of very high wind speed, owing to its limited length, and hence
294 could not predict the return period values for these cases. However, from the IMAGE
295 simulation such return periods can also be estimated. A similar result occurs for the case of
296 very low wind-speed.

297

298 This analysis of return periods is validated by the observation that the relatively frequent
299 events with return periods much smaller than a year have similar distributions in both the
300 ERA5 reanalysis and IMAGE simulations (Figure 5A and B). Furthermore, in the past 41
301 years, in the ERA5 reanalysis Box A had a record average daily wind speed of 12.25 m/s
302 only once and the median return period of this high wind speed is predicted as 33 years by
303 IMAGE. Similarly, Box B experienced only one record instance of average wind speed
304 beyond 12.25 m/s in 41 years in the ERA5 dataset and the median return period of this event
305 is predicted as 60 years by IMAGE. For Box B IMAGE can simulate extreme low wind
306 speed of 1.25 m/s with a return period of 30 years. This is outside of the observed range and
307 illustrates the benefits of the IMAGE model.

308

309 **5: Results**

310

311 **5.1 Probability of low wind or “wind drought” in India**

312

313 In a future electricity grid in which the share of wind energy is large, the probability of low
314 wind (“wind drought”) across large parts of the grid is a critical concern. Rajasthan and South
315 India significantly comprise India’s two distinct wind rich regions. Since wind development

316 is likely to concentrate substantially in these regions, we examine the association between
317 low wind days in both of these regions. IMAGE simulations over a period of 1000 years
318 indicate that, on days when Box A (Rajasthan) experiences low wind on average (below 3
319 m/s), there is only 0 to 10% probability that locations in Box B (South India) will have wind
320 lower than 3 m/s (Figure 6A). Low wind in Box A occurs in 7% of the days in 1000 years.
321 Similarly, on the days when Box B has low wind, with average below 3 m/s, there is only 10
322 to 20% probability that individual locations within Box A will also have low wind (Figure
323 6B). Low wind in Box B occurs 6% of the time in 1000 years. Clearly, these two regions
324 demonstrate a complementary behaviour from the perspective of “wind drought”. Hence,
325 there is a possibility of avoiding grid-wide wind droughts if regional grids in these two
326 regions are themselves connected. This is illustrated further with the help of a case study.

327

328 **5.2 Case Study**

329

330 Four sets of paired locations from Box A (Rajasthan) and Box B (South India) are chosen for
331 the case study. As Box A and Box B demonstrate a complementary behaviour from the
332 perspective of “wind drought”, these sets of pairs are chosen accordingly. Daily generation
333 from one wind turbine was simulated for each location depending on the local wind speed.

334

335 Set 1: One grid having maximum mean wind speed in Box A and another neighbouring grid

336 Set 2: One grid with maximum mean wind speed in Box B and another neighbouring grid

337 Set 3: Grids with maximum mean wind speed in each of the boxes

338 Set 4: Grids with second highest mean wind speed in each of the boxes

339

340 We estimate the fraction of days with zero generation in the 1000 year IMAGE simulations,
341 for the individual plants and with the combination of the two plants, one in each of the
342 chosen grids. In the case of Set 1, the individual plants in Rajasthan have 11% and 15% of
343 days with zero generation, while the combination of these two plants has 10% of days with
344 zero generation. Similarly, in the case of Set 2, the individual plants in South India have 11%
345 and 9% of days with zero generation, whereas the combination of these two plants has 5% of
346 days with zero generation (Table 1). These two case studies demonstrate that in case of wind
347 plants situated nearby, such as in a neighbouring grid, their aggregate generations do not
348 show much improvement as measured by the fraction of days with zero generation. This
349 occurs because low wind days tend to coincide for the grids that are located in the same box
350 or within small regions.

351

352 The next two sets (3 and 4) show the benefits that can be achieved by combining wind plants
353 that are located in different regions (Box A - Rajasthan and Box B - South India). In the case
354 of Set 3 (Combination of grids with maximum mean wind speed from each of the boxes A
355 and B) we estimate the fraction of days with zero generation in the 1000 year IMAGE
356 simulations for each individual locations as well as their combination. We found that while
357 the plants in Boxes A and B experience 11% and 9% of days with zero generation, the
358 combination of these two plants experiences only 1% of days with zero generation. Set 4
359 considers the combination of grids with second highest mean wind speed from each of the
360 boxes A and B. Similar estimations were made for set 4. We found that for Set 4, while the
361 individual plants have 15% and 11% of days with zero generation, their combination has only
362 2% of days with zero generation (Table 1). In the cases 3 and 4, improvement in fraction of
363 days with wind drought for the combined generation is evident because low-wind days in
364 each of the two regions (A and B) coincide less frequently.

365

366 The next part of the case study further examines the reduction in fraction of “no generation”
367 days, and Figure 7 depicts the results. After identifying the 20 grids with highest mean wind-
368 speeds in Boxes A and B, we simulate the aggregate generation from all possible
369 combinations of 4 grids chosen from these 20. The boxplot indicates the reduction in fraction
370 of zero generation days in 1000 years due to aggregation of different combinations of four
371 wind plants from different Boxes (A and B); Combination AAAA has all four grids from Box
372 A, while combination AABB has two grids from each boxes (Box A and Box B). The bold
373 black line is the median for the improvement for each set of combinations. The top and
374 bottom of the boxes indicate the 75th and 25th percentile values for each combination.
375 Combination of plants from different regions (AAAB, AABB, BBBA) demonstrates larger
376 reduction (0.13 to 0.14 (median)) in fraction of “no generation” days by aggregation of
377 generation compared to plants located in same region (AAAA, BBBB) (reduction of 0.1).

378

379 **6: Discussion and Conclusion**

380

381 The IMAGE weather generator has been validated for wind-power studies over India. The
382 weather generator has been able to reproduce the statistics of ERA5 reanalysis over the
383 region. We tested the output for 40 grid locations, chosen because of their proximity to in-situ
384 wind measurements from NIWE. The weather generator could correctly reproduce the mean
385 wind and seasonality. The key advantage of the underlying model is that it can also capture
386 the pairwise temporal correlation between sites. We confirmed that the correlation between
387 sites is correctly captured by IMAGE. The model was then trained on wind-speed time-series
388 from ERA5 reanalysis wind data to gain insight into the correlated behaviour of wind-
389 droughts in the important wind resource regions of Rajasthan and South India. Our emphasis

390 in this paper is on noting the value of a new tool for studies of renewable drought over the
391 region, using the relevant gridded datasets, not limited to ERA5. Other datasets, such as the
392 regional high-resolution analysis, IMDAA, can also be used as inputs to IMAGE. The benefit
393 of a stochastic weather generator is that it can simulate out-of-sample events to get a more
394 robust estimate of, for example, 100 year and other low probability events. A 1000-year
395 simulation of daily wind-speeds allows us to quantify the likelihood of wind droughts
396 anywhere in India.

397

398 A potential implication of such studies is to that they can be used to quantify benefits of
399 strong grid interconnections across weakly correlated regions. In our case study, we find that
400 the risk of a wind drought in one region could be substantially mitigated by supplying wind
401 from another region. We find cases where the number of days with no power generation can
402 be dramatically reduced by a factor of 10 if the regions were interconnected. Stochastic
403 models have long been used in the hydrological community^{15,16}. Our study shows that it can
404 also be useful for wind risk assessment in India and very likely elsewhere.

405

473 **Table 1.** Impact of aggregation of simulated wind generation from different plants on the
 474 fraction of days with “no generation” in IMAGE simulations of 1000 years; **a)** Set 1: plants
 475 located in Box A; Moderate improvement in no generation days; **b)** Set 2: plants located in
 476 Box B; Moderate improvement in no generation days; **c)** Set 3: Plants located in grids with
 477 maximum mean wind speed in Box A and B; **d)** Set 4: Plants located in grids with second
 478 highest mean wind speed in Box A and B; In the last two cases, improvement is evident
 479 because low-wind days in each of the two regions coincide less frequently.

480

Sets	Percentage of days with “no generation” in 1000 years		
	Plant 1	Plant 2	Combination
a) Set 1	10%	14%	9%
b) Set 2	11%	8%	5%
c) Set 3	10%	8%	1%
d) Set 4	14%	11%	2%

483 **Figure legends**

484 **Figure 1.** Mean climatological wind speed at 100m above ground over India; Purple dots
485 show 40 locations chosen for validation from wind rich regions; These 40 locations are used
486 for ERA5 comparison with in-situ data and IMAGE validation; The green triangles indicate
487 three locations out of these 40 locations that are chosen for validating seasonal pattern
488 simulated by IMAGE; Brown boxes indicate the areas chosen for validation of return period
489 of various wind speed from the simulation with respect to ERA5 input; These same regions
490 are used for demonstrating the application of IMAGE.

491 **Figure 2.** Comparison of climatology ERA5 wind speed with observation data from NIWE
492 for year 2014; A) Comparison of daily mean wind speed for 40 NIWE wind monitoring
493 stations in wind rich regions of India; B) Comparison of monthly wind speed pattern for a
494 NIWE wind monitoring station, Devereddyalli; The red dot indicates the monthly median
495 wind speed from 41 years of ERA5, the vertical line shows the distribution; Although, ERA5
496 underestimates the wind speed, the seasonal pattern is captured accurately.

497 **Figure 3.A)** Comparison of mean wind speed simulated by IMAGE with ERA5 input
498 dataset; the R square value is 0.99, and the bias is small; Each point indicate median values
499 for an individual location. The vertical bars show the distribution across 100 ensemble
500 members, each being as long as the input data (41 years); The $x = y$ line is shown in black; **B)**
501 Comparison of wind-speed spatial correlation between each of 40 locations and Dhanuskodi
502 as simulated by IMAGE, with corresponding correlations from ERA5 input dataset; the R
503 square value is 0.99; Each point indicates median values across 100 ensemble members,
504 while vertical bars show the distribution; The $x = y$ line is shown in black. **c)** Comparison of
505 monthly average wind speed pattern simulated by IMAGE with corresponding values from
506 the ERA5 input dataset at three high-wind locations: Dhanuskodi, Devereddyalli and Bassi.

507 **Figure 4.** Comparison of the probability distribution and best-fit Weibull curves based on
508 ERA5 and IMAGE, **A)** Gudaparihar (Weibull shape factor = 3.19, scale factor = 5.31); Based
509 on IMAGE simulated daily wind speed for 4100 years (4100 x 365 data points); **B)**
510 Gudaparihar (Weibull shape factor = 3.19, scale factor = 5.31); Based on ERA5 based 41
511 years of daily wind speed **C)** Bassi (Weibull shape factor = 3.04, scale factor = 4.97); Based
512 on IMAGE simulated daily wind speed for 4100 years (4100 x 365 data points); **D)** Bassi
513 (Weibull shape factor = 3.04, scale factor = 4.97); Based on ERA5 based 41 years of daily
514 wind speed.

515 **Figure 5. A)** Return period (x-axis) of daily average wind speed (y-axis) over Rajasthan from
516 ERA5 reanalysis and IMAGE simulations; **B)** Return period (x-axis) of daily average wind
517 speed (y-axis) over South India from ERA5 and IMAGE simulation; The points indicate the
518 median return periods while the horizontal lines show the distribution of return periods.

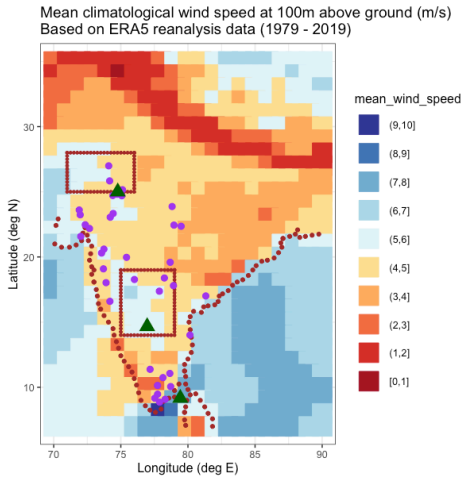

519 **Figure 6. A)** Fraction of days wind speed is below 3m/s in individual pixels across India
520 when Box A (shown in black) has a wind low. Analysis is based on 1000 years of IMAGE
521 wind speed simulation; The blue colour represents fewer days with wind-drought; **B)**
522 Fraction of days wind speed is below 3 m/s in individual pixels across India when Box B
523 (shown in black) experiences a wind low.

524 **Figure 7.** Reduction in fraction of zero generation days in 1000 years due to aggregation of
525 different combinations of four wind plants from different Boxes (A and B); Combination of
526 plants from different regions demonstrates larger improvement in fraction of “no generation”
527 days by aggregation of generation.
